## Introduction

Thermoregulation or heat regulation by definition means the regulation of body temperature in order to maintain bodily function, which for humans is ~37 °C or 98.7 °F (Lim et al. 2008; Tansey and Johnson 2015). The most common and accurate method of core body temperature measurement is via rectal probe thermometer (Osilla and Sharma 2018). Thermoregulation is the part of hemostasis process of an organism, which is the state of equilibrium. From an evolutionary point of view, thermoregulation is considered an important step, helping such organisms to survive more easily in adverse environmental conditions. The hypothalamus is considered as the regulatory center for the body temperature maintenance and is therefore called the body’s thermostat (Romanovsky 2007). In addition, endocrine system glands like the pineal gland in ectotherms (Lutterschmidt et al. 2003) and thyroid gland in endotherms (Silva 2006) play key roles in thermoregulation.

On the ability of maintaining their body temperature within a limit, there are two major groups of organisms, ectotherms/cold-blooded animals and endotherms/warm-blooded animals. Thermoconforming organism/ectotherms are the organisms that cannot maintain their body temperature in a

confined range, and their body temperature fluctuates with the external environmental temperatures, such as fishes, amphibians, and reptiles (Kearney et al. 2009). These organisms cannot survive for long if there is a continuous alteration in their surrounding environment, and they are subjected to hypothermia in case of extreme lower temperature and hyperthermia in increased temperatures, which might lead to failure in normal body functions and ultimately death (Mallet 2002). In contrast, endotherms maintain their body temperature in a narrow range irrespective of the external temperatures, such as birds and mammals (Ivanov 2006). The major pathways as well as key regulators are conserved in both ectotherms and endotherms. External temperature is sensed by transient receptor potential ion channels, and the information is then relayed on to the hypothalamus, which initiates a sympathetic efferent response (Seebacher 2009).

Mechanism and Counteractive Strategy

There are various mechanisms for thermoregulation in endotherms.

Under increased temperature, the body starts sweating, and vasodilation occurs, which increases the blood flow to further cool down the body (Schmidt and Chan 1992). In contrast, under

decreased temperatures, shivering occurs, which produces heat in the body (Charkoudian 2010). In addition, vasoconstriction decreases the blood flow under the skin retaining heat of the body (Charkoudian 2010).

Some animals enter a state of dormancy minimizing their metabolic activities under unfavorable environmental conditions. In colder temperatures, some mammals undergo hibernation, for example, polar bear, bats, lemur, alpine marmots, etc. In order to sustain their energy needs during the hibernating period, these animals store extra fat in form of brown fat/brown adipose tissue, which produces heat by non-shivering thermogenesis (Van der Lans et al. 2013). A similar process is aestivation, which occurs in warm temperatures and in a variety of organisms like fat-tailed lemur, desert tortoise, spotted turtle, California tiger salamander, water-holding frog, bees, earthworms, and lady bugs (Table 1).

Diagnosis

In order to detect any abnormalities in maintaining the body temperature, a thermoregulatory sweat test (TST) is carried out by analyzing sweat production in a controlled environment. The sweat production pattern of an individual in

Thermoregulation, Table 1 Different adaptive strategies acquired by ectotherms and endotherms

| Thermoregulation       | Ectotherm                                                               | Endotherm                                                                           |
|------------------------|-------------------------------------------------------------------------|-------------------------------------------------------------------------------------|
| Under warm temperature | Evaporation of body fluids like sweat                                   | Evaporation of body fluids across respiratory surfaces or skin through sweat glands |
|                        | Vasodilation to increase blood flow to dissipate heat from body surface | Perspiration and panting in cats and dogs                                           |
|                        | Coming in contact with a cold surface                                   | Gular fluttering in birds                                                           |
|                        |                                                                         | Living in burrows during the day and being nocturnal                                |
|                        |                                                                         | Stretched body position and loss of appetite                                        |
|                        |                                                                         | Decreased metabolic rate                                                            |
| Under cold temperature | Changing shape to alter surface/volume ratio                            | Increased metabolic rate                                                            |
|                        | Lying in the sun                                                        | Blubber in whales works as insulating layer                                         |
|                        | Coming in contact with a hot surface, water stream                      | Subcutaneous fat in humans                                                          |
|                        | Folding skin to reduce heat loss                                        | Goose bumps provide hindrance in air flow across skin and minimize heat loss        |
|                        | Natural antifreeze or antifreeze proteins                               | Huddled body position and increased appetite                                        |

addition to the central and autonomic nervous system activities is noted through digital photography. Any abnormalities whether in sweat production or inability to respond to increasing or decreasing temperatures are then revealed.

## Introduction

The evolution of intelligence in our own and other species remains a hotly debated topic. The social brain hypothesis, prominent in this debate, argues

that one of the reasons animals have acquired increasingly complex cognition (i.e., intelligence) is to deal with increasingly complex social life (Dunbar 1992; Humphrey 1976). Studies have found a relationship between interspecific variation in primate neocortex size and group size (Dunbar 1992) and more generally in mammalian brain size and respective group sizes (Shultz and Dunbar 2010a). Moreover, studies show that gray matter density in particularly “social” parts of the brain correlates significantly with social network size in humans (reviewed in Adolphs 2009) and rhesus macaques (Noonan et al. 2014). Importantly, intraspecific variation in group size also predicts cognitive performance in several different taxa (Ashton et al. 2018).

However, the question remains: which challenges in social life necessitate increased cognitive capacity? Notably, the interspecific correlation between brain size and group size does not hold for all mammal species, nor does it hold for avian species (Shultz and Dunbar 2007, 2010b); thus, group size per se might be too simplistic to explain species differences. Consequently, many scholars have focused their attention on species’ “social complexity,” yet the term has remained relatively vague and it is currently undecided what actually constitutes social complexity (cf. Boucherie et al. 2019). In his seminal paper on social relationships, Robert Hinde (1976) identified three levels of increasing complexity in the social life of an individual, i.e., (1) interactions, (2) relationships (described by the content, quality, and patterning of interactions), and (3) the structure of a group, based on the patterning of relationships. More recently, this framework has been expanded by the spatiotemporal dynamics of a species, i.e., the degree to which the social environment of an individual varies across time and contexts (cf. fission-fusion dynamics, Aureli et al. 2008), lifetime changes to the social environment (Boucherie et al. 2019), and the role of interactions with conspecific outsiders (Ashton et al. 2020).

Social complexity, in all these conceptions, assumes that individuals have repeated interactions with group members as agents with their own interests, history, and relationships; and individuals have to compromise between competition

for resources and the need to cooperate to survive. Accurately predicting conspecific behavior – by keeping track of others’ social interactions and relationships – could give individuals an advantage but would dramatically increase individuals’ information processing needs when navigating the social landscape (Dunbar 1992). Thus, one central aspect to the study of comparative social complexity has been a focus on third-party interactions. Third-party interactions are any situation where two group members interact, and a third individual influences the course, outcome, or aftermath of the interaction. These situations remind us that individuals in social groups are engaged actors that influence the lives of others. In terms of complexity, the possibility that other group members can get involved dramatically increases the number of social situations that can occur in a group; it forces animals to be vigilant about their surroundings, and it might allow them to strategically manipulate the interactions and relationships of others in a process of social niche construction (Flack et al. 2006). For researchers, third-party interactions open up a window into the mind of our study species: we can test what they know about the power relations and bonds between those in their group and which interactions they perceive as relevant (Bergman et al. 2003). Here, we will summarize evidence that many social animals are indeed able to classify the relationships between others in their group along multiple dimensions and will proceed to describe how they use this knowledge to intervene into aggressive and affiliative interactions. We provide seminal and clear examples but want to emphasize that the list of studies we refer to is far from exhaustive.

## Understanding Third-Party Relationships

On their own, interactions between conspecifics do not need to involve complex cognition. An evaluation of the motivation, strength, sex, and age of your interaction partner may do the trick. Whenever these interactions occur more often with certain individuals, however, it may pay off to individually recognize and differentiate

between individuals, leading to variation in relationship quality. This becomes particularly important when individuals repeatedly cooperate with group members in reciprocal exchanges. Various social species entertain such differentiated social relationships; recognize others as kin, friend, and/or dominant; and remember such relationships over time (Massen et al. 2010). However, do animals also recognize the patterning of social relationships among their conspecifics, i.e., do they also know who is related to whom and who outranks whom? This could allow them to predict behavior more accurately.

In a seminal study, Dorothy Cheney and colleagues (1995) investigated whether yellow baboons understand power relationships of others. In a cleverly designed experiment, they made use of the vocal cues accompanying dominance interactions among the baboons; that is, dominant individuals tend to grunt to subordinate individuals, who occasionally respond with fear barks. Importantly, this never happens in the other direction. Cheney and colleagues made recordings of grunts and barks and then edited them to create *expected* sequences of a dominant individual grunting and a subordinate individual fear barking, thus according to the dominance hierarchy. However, they also created *unexpected* sequences of a subordinate grunt followed by a fear bark from a dominant individual, thus inconsistent with the current dominance hierarchy. As such, this sequence could mimic a turnover in the group's dominance hierarchy. They then played back these sequences and monitored the reactions of third parties, i.e., individuals that were not part of the simulated interaction. The baboons reacted much stronger to unexpected sequences, suggesting that the baboons have certain expectations about third-party dominance interactions between group members (Cheney et al. 1995) and thus seem to have some sort of mental representation of these dominance relationships.

However, in principle, the baboons could also deduce the relationship between others by comparing their own relationship with each of them separately. For example, if individual A is dominant over our subject and individual B is subordinate to the subject, the subject can deduce that A is

dominant over B. Such transitive inference in itself is already an interesting cognitive feature. It becomes more complicated if both are dominant over, or subordinate to, the subject, but then still the subject could deduce the relationship between A and B by comparing the rank distance or degree of dominance/subordinance with each of them and thus without requiring a mental representation of the relationship between those others. Nonetheless, since then, experiments using similar play-back setups have shown that chacma baboons differentiate third-party rank relationships within and between family groups and thus seem to classify their conspecifics simultaneously based on their individual rank and their kin relations (Bergman et al. 2003), which do not need to overlap with the subjects' kin relationships. Moreover, captive ravens showed that they not only have expectations about the rank relationships in their own group but that they also seem to understand the rank relations of a neighboring group (Massen et al. 2014a). They could observe that group but did not have any direct relationship with them, suggesting that these ravens do have some sort of mental representation of rank relations.

### Third-Party Interactions

Having third-party knowledge becomes particularly adaptive if used strategically to outcompete your conspecifics. Specifically, animals may interfere in ongoing interactions between other individuals. These interactions allow individuals to affect the outcome of social interactions to their own benefit: presumably, the potential outcome could have negative consequences for a bystander (e.g., their offspring is injured; a competitor creates a new alliance), and they have the power to influence the outcome to their own benefit. Broadly, third-party interactions allow group members to maintain the status quo (by stabilizing group dynamics, enforcing existing alliances, and preventing new alliance formation) but can also be used to challenge existing power structures (by, for example, combining forces against higher-ranking competitors and gaining access to new cooperation partners).

The third party can interfere in aggressive conflict or in affiliative/cooperative interactions. Different terms have been used to describe third-party interactions, dividing them by the nature and direction of the third party's involvement. During aggressive interactions, individuals can provide *coalitionary support* (third-party aggression toward one of the opponents) or engage in *policing* (impartial third-party action to stop conflict). After conflict, they can provide *third-party post-conflict affiliation* ("third-party reconciliation" if they perform reconciliation for a friend or kin; "consolation" or "triadic post-conflict affiliation" if they direct affiliation toward the loser of the conflict). Also, *third-party interventions in affiliative interactions* (attempting to disrupt or participate in affiliative interactions) have been described in an increasing number of species. We will describe each of these categories in the remainder of this chapter.

## Support in a Conflict

Possibly the best-described form of third-party interaction is support in a conflict (de Waal and Harcourt 1992). Coalitionary support has been described in a range of animal species (Bissonnette et al. 2015) and has been cited as one of the prime examples of nonhuman animal cooperation if individuals risk injury by interfering (van Schaik et al. 2004). However, whether this is a truly cooperative endeavor depends on the context and the opponents involved. Possibly the most common form of coalitionary support, for example, involves the opportunistic support of a high-ranking individual that is attacking an individual that is lower ranking than both the coalition partners ("all-down" coalitionary support), thereby enforcing the status quo. Consequently, the chances of losing the fight and/or the risk of injury are low (van Schaik et al. 2004). As the support of high-ranking group members is a strong factor in winning conflicts, most species who show coalitionary support also show targeted recruitment behavior (e.g., Range and Noë 2005).

Nevertheless, coalitionary support may also occur between an individual that is higher in

rank than the opponent and one that is lower in rank than the opponent ("bridging coalition"), or both coalition partners are outranked by the opponent ("all-up coalition"). Support might result in rank changes or levelling of access; that is, they provide temporary access to resources otherwise restricted by the higher-ranking individual target. In some species, coalitionary support against high-ranking individuals is central in the attainment of dominance rank (de Waal 1982). Whether animals engage in such coalitions depends not only on the species and potential cognitive constraints but also on the context (van Schaik et al. 2004). The decision to support one side in a fight is probably based on an evaluation of the feasibility (i.e., the potential to win), the costs for both participants (likelihood of injury), the benefits it will provide for both participants, and the relationship with the potential coalition partner, where friends are more likely to support each other (Schino 2007).

## Policing

While ample evidence exists that individuals in a variety of species intervene in aggression to support one side, few descriptions of neutral or impartial interventions ("policing") exist, and published studies so far are generally in primates. Policing interventions (first described by de Waal 1982) do not target either contestant but terminate the aggression itself and prevent opponents from restarting the conflict. Policing is used by individuals to manage conflict in their community, stabilize the group, and prevent drawn-out fights or injuries that would hurt the group as a whole (Flack et al. 2006).

The scarcity of information on policing might be a reflection of its rarity or a result of the difficulty of deciding whether an intervention had a specific target or not. Policing behaviors have been described as such mainly in different species of macaque (Beisner and McCowan 2013; Flack et al. 2006) and chimpanzees (von Rohr et al. 2012). Usually, higher-ranking group members will attack both the opponents and/or position themselves between them, thereby disrupting

conflict, even though (usually lower-ranking) female chimpanzees are sometimes also involved in impartial interventions (von Rohr et al. 2012). Policing seems to occur when the costs for the policer are low, for example, when they outrank the opponents, but they also do not seem to confer directly measurable benefits (Beisner and McCowan 2013). This has led to theorizing that policing mainly functions to stabilize the group – experimentally removing frequent “conflict managers” from a group increased the number of aggressions and reduced grooming and reconciliation rates within the group (Flack et al. 2006).

### Post-conflict Affiliation

Originally dubbed consolation (de Waal and van Roosmalen 1979), triadic post-conflict affiliation describes affiliative approaches of a third party directed toward a former conflict participant. Among great apes, this may be reflected in an embrace, much like we humans console others. The definition of post-conflict affiliation by bystanders has since been extended to encompass multiple functions: to reduce stress in the victim (“true” consolation and sometimes considered an expression of empathy); to reduce the likelihood that aggression escalates and the bystander becomes a victim themselves; or to reconcile the opponents indirectly if the bystander is bonded or kin with either.

Third-party post-conflict affiliation has been described for a range of primate (reviewed in Watts et al. 2000) and non-primate species (see Fraser and Bugnyar 2010). Its function seems context specific and to vary both between and within species (Fraser et al. 2009). For example, in chimpanzees, former conflict victims show reduced behavioral markers of stress after triadic post-conflict affiliation (i.e., according to the definition: consolation; Fraser et al. 2008), whereas another study found that chimpanzees show this behavior to protect themselves from redirected aggression of that former victim (Koski and Sterck 2007).

The function of triadic post-conflict affiliation seems highly dependent on the quality of the

relation between the former conflicting individuals and the third party. High relationship quality between the third party and the victim may lead to actual consolation; the victim outranking the third party may lead to protection against redirected aggression; and finally kinship or friendship between the former opponent and the third party may lead to third-party reconciliation (Fraser et al. 2009). Triadic reconciliation (Judge 1991) can happen when a third party that is a relative of one of the opponents in a conflict approaches and affiliates with that other former opponent in the conflict and is suggested to aid in the repair of the relationship between the former opponents and in stress alleviation, much like reconciliation between the two former opponents.

### Affiliation Interventions

An increasing number of studies has shown that affiliative or cooperative interactions can also be subject to outside interference (first reported in de Waal 1982). Affiliative interactions are ubiquitous in many animal species, especially those with repeated interactions between conspecifics in more or less stable associations as we see in many mammals and birds (Massen et al. 2010). Social relationships are negotiated through a number of low-cost cooperative exchanges (“affiliations”), such as grooming, allo-preening, play, huddling against cold, vocal exchanges, and so on (Massen et al. 2010). Each individual usually only has a small number of close partners as the time for affiliation and resources individuals can provide in return are limited, leading to competition over access (Seyfarth 1977). Thus, affiliative interactions between two individuals have at least three potential, immediate consequences for a bystander:

- (A) The affiliation limits the amount of time these individuals have available.
- (B) The affiliation might threaten the bystander’s social bonds with either partner because they might indicate a shift in bonding effort.
- (C) The affiliation might indicate a change in power dynamics in the group if high-ranking

individuals provide aggression support to immediate competitors of the bystander.

There is increasing evidence that all three of these reasons might trigger bystanders to influence the course and outcome of affiliative interactions of group members. How interventions play out and what bystanders can do to intervene differ between species: individuals might disrupt the affiliation completely; they might supplant one of the partners and take over their role; or they might become part of the affiliation (e.g., by joining a play bout).

The effects of competition over attractive partners (A) have been studied indirectly in many species, by studying the distribution patterns of aggregated cooperation rates in relation to dominance rank (following Seyfarth 1977). Recently, more direct evidence for competition for cooperation partners has been added: For example, grooming interventions in several primate species are driven by individuals that outrank at least one groomer and subsequently gain access to the higher-ranking groomer, thus establishing their own priority of access and potentially preventing revolutionary alliances (e.g., Range and Noë 2005). Importantly, in these interventions, the intervener ultimately gains access to one of the groomers – their motivation could therefore simply be driven by their own desire to groom an attractive partner.

In contrast, animals may also intervene in affiliative interactions that threaten their own existing relationships (B). Many social animals rely heavily on social bonds for survival and competition (Massen et al. 2010). It is therefore not surprising that interventions are used to protect these bonds from outside interference. For example, in feral horses, female bystanders challenge individuals who are affiliating with the bystander's close social partners. This is facilitated if the bystander is of higher rank than the competitor, but the motivation seems to be to prevent bond partner defection, because the intervener does not subsequently groom the partner (Schneider and Krueger 2012). Similar patterns have been observed in some primate species. In sooty mangabeys, Western chimpanzees, and

rhesus macaques, bystanders are more likely to intervene into a grooming bout when they have a strong social bond with either groomer (Mielke et al. 2017, 2021). Domestic dogs display interventions in experimental situations where their owner affiliates with a dog-like toy, a result that has been likened to jealous behavior in humans (Harris and Prouvost 2014). Similarly, captive chimpanzees, just like their wild counterparts, intervene into affiliations when new group members target existing bond partners and show a strong negative emotional response that would indicate feelings of jealousy (Webb et al. 2020). Affiliation interventions are therefore not only a useful tool for the study of animal decision-making but also potentially of the evolution of emotions.

Finally, besides disrupting bond formation of their own friends, individuals can use affiliation interventions strategically to disrupt competitors from using alliances to shift power balances (C). Interventions of affiliative interactions can be highly effective in sabotaging ongoing affiliation (Mondragón-Ceballos 2001). In common ravens, pair-bonded individuals prevent the formation of new pair bonds, as the resulting pair would potentially lead to changes in the dominance hierarchy that could be detrimental to the intervener (Massen et al. 2014b). Similarly, sooty mangabeys, chimpanzees, and rhesus macaques show interventions at higher rates when the lower ranking of the two groomers is close to them in rank (after controlling for kinship and social bonds), indicating that they prevent competitors from accessing high-ranking partners (Mielke et al. 2017, 2021). Thus, like policing, affiliation interventions enable animals to preserve the status quo in their social groups.

To summarize, evidence of third-party understanding and the use of this knowledge in third-party interactions is accumulating for a variety of species, giving us a glimpse of the complexity of life in a social group and the cognitive abilities of many animal species. The function of these behaviors varies depending on the interaction, species, and context and generally depends a lot on the relationship quality of the three parties involved. Moreover, some third-party interactions

can be flexibly applied to different context. Consequently, it has been hypothesized that the need for such flexible and strategic cognition in social groups with increasing complexity has been a significant selection pressure in the evolution of intelligence. While the focus of third-party interactions has long been on conflicts and post-hoc conflict management, it now seems clear that third parties can influence all manner of social interactions in a group (aggression, affiliation, play, sex, etc.). This creates a rich tapestry of interactions giving individuals the opportunity to influence their social environment, and we are very much looking forward to how further results from a wider variety of species and contexts will shed more light on individual animals as social agents.

## Thyroid and Adrenal Glands

Jonathan H. Pérez and Jesse S. Krause  
Department of Neurobiology, Physiology, and Behavior, University of California, Davis, CA, USA

### Definition

**Thyroid gland:** a collection of follicular cells surrounding a colloid space that concentrate dietary iodine and produce the thyroid hormones thyroxine (T4) and triiodothyronine (T3). Individual follicles may or may not be organized into a larger structure depending upon taxa.

**Adrenal gland:** endocrine gland located next to the kidney responsible for production of a number of hormones including the glucocorticoids as well as the catecholamines.

## Thyroid Gland

### Introduction

The thyroid gland and its products thyroxine (T4) and triiodothyronine (T3) are present across vertebrate taxa. As with all endocrine glands the thyroid is ductless and highly vascularized and thyroid hormones are excreted directly into circulation upon secretion. The thyroid gland is unique among the endocrine glands because of its dependence upon dietary iodine for hormone production and its ability to concentrate and store dietary iodine.

### Anatomy

Though functionally highly conserved, the location and gross anatomy of the thyroid gland varies across vertebrate taxa. Generally in most taxa, the gland(s) are located within the neck region, though the precise location varies. The exception to this rule is the *Echidna* in which the thyroid is present as a pair of unattached glands located in the thorax. In cyclostomes and most teleosts, the gland is disorganized with follicles scattered in the region of the pharynx (Gorbman et al. 1983). In frogs, amphibians, mammals, and birds, the gland exists as a two separate lobes that occur bilaterally. In mammals and humans, in particular, it is composed of two distinct lobes connected by an isthmus, located in the anterior portion of the neck lying on the trachea between vertebrae C5 and T1 (Gorbman et al. 1983). With the exception of the cyclostomes and teleosts in which the gland is disorganized, the thyroid gland, regardless of gross anatomy, is comprised of small spherical follicles. These follicles are formed by a layer of epithelial follicular cells surrounding the follicular lumen (a.k.a. follicular or colloid space), an open space that is filled with fluid-like colloid. Regardless of organizational structure, the resulting thyroid follicles are highly vascularized to support both iodine uptake and secretion of its hormonal products.

## Iodine Uptake

Production of thyroid hormones begins with the active uptake of iodine by the thyroid gland. Concentration of iodine within the gland against its concentration gradient is accomplished by active transport of iodine by and  $\text{Na}^+/\text{I}$  symporter. The end result of this active transport is the concentration of iodine within the colloid space of the follicles.

## Production of Thyroid Hormones

Thyroid hormone production begins with the synthesis of thyroglobulin, an approximately 660-kDa glycoprotein homodimer, in the endoplasmic reticulum of follicular cells. Thyroglobulin is stored within the follicular lumen, where the enzyme thyroid peroxidase (TPO) catalyzes the iodination of the tyrosine residues to form either mono-iodinated or di-iodinated tyrosine residues. Subsequently, coupling of iodinated tyrosine residues results in the formation of T3 and T4 residues. The iodinated thyroglobulin is stored within the follicular lumen until needed. In response to central signaling from the brain, iodinated thyroglobulin molecules are endocytosed into the follicular cells and the iodothyronine residues are cleaved to create T4 and T3, which are then secreted into circulation. Typically, T4 forms the vast majority of the hormone secreted into circulation while T3 comprises only a small fraction.

## Central Control of Thyroid Hormone Production and Signaling

Thyroid hormone production and secretion is controlled by the hypothalamic–pituitary–thyroid (HPT) axis. Neural inputs of both environmental and internal stimuli are integrated in the brain and cause stimulation of the parvocellular neurons in the paraventricular nucleus of the hypothalamus triggering the release of thyrotropin-releasing hormone (TRH) that acts on thyrotroph cells in the anterior pituitary to cause the release of thyroid-stimulating hormone (TSH). After entering the blood stream, TSH binds to the G-protein–coupled receptors of the follicular cells, triggering the release of thyroid hormones from the follicular cells, and stimulates increased iodine

uptake and thyroid hormone synthesis by the gland. The activity of the HPT axis is controlled though classic negative feedback mechanism, in which circulating thyroid hormones bind to receptors in parvocellular neurons in the arcuate nucleus of the hypothalamus and the thyrotroph cells in the anterior pituitary gland to reduce the activity of these two points in the hormonal axis.

## Carrier Proteins

As with most hormonal systems, thyroid hormones are subject to multiple levels of regulation beyond central control of production and release. Following secretion from the thyroid gland, circulating hormones become bound to carrier proteins, which form the bulk of the hormone in circulation (Yen 2001). There are three major carrier proteins for thyroid hormones: thyroid-binding globulin, transthyretin (TTR; previously TBPA), and albumin (Larsson et al. 1985). TTR is of particular interest as it is found not only in circulation, but expression has been identified in other tissues including the liver and choroid plexus of birds (Power et al. 2000). Binding to carrier proteins protects bound hormone from enzymatic degradation and clearance, but also limits its ability to enter cells and bind to target receptors, thus controlling in part cellular exposure to bioactive hormone.

## Membrane Transporters

Until recently, dogma held that thyroid hormones were able to enter target cells via passive diffusion across the plasma membrane (Robbins and Rall 1960). However, recent work has uncovered a large array of membrane transporters that actively transport thyroid hormones across the plasma membrane. At present, over 21 different transport proteins have been identified with varying degrees of specificity for the iodothyronine derivatives: including organic anion-transporting polypeptide transporters (e.g., OATP1C1), monocarboxylate transporter family members MCT8 & MCT10, and L-type amino acid transporters (reviewed in Visser et al. 2011). While these transporters are beginning to be characterized in mammalian systems, little is known about their

distribution, functionality, or expression patterns in most other taxa and broad-scale comparative work is completely lacking. However, the need for membrane transport of thyroid hormones allows for a wide array of potential regulatory schema. Evidence has emerged from multiple species identifying expression of transport proteins in the brains of rats and birds, particularly in the blood–brain barrier. Expression of transporters in the blood–brain barrier with differential specificity for T3 versus T4 may be critical for regulating whole brain exposure to thyroid signaling, particularly in conjunction with deiodinase regulatory activity.

### Regulatory Enzymes

Though T4 is the major product of the thyroid gland in circulation, receptor binding studies have shown that thyroid hormone receptors (THR $\alpha$ s) have significantly higher affinity for T3 as compared to T4; thus, T3 has long been considered the bioactive form of the hormone with T4 often being considered a precursor hormone. The conversion of T4 to T3 is under the control of the second major level of thyroid hormone regulation, the deiodinase enzyme system. This system is comprised of three enzymes: deiodinases type I, II, and III (DIO1, DIO2, DIO3), which function by removing iodine from different positions. All three deiodinases require selenium for functional catalytic activity; thus, either dietary deficiency or defects in synthesis of selenoproteins results in various defects in deiodinase activity and negative feedback control of the HPT axis. Despite these basic similarities, these three enzymes differ in their distribution and the reactions they catalyze. Found primarily in the liver, kidney, and thyroid gland itself, DIO1 is capable of deiodinating both the inner and outer rings of thyroid hormone molecules, thus catalyzing both the conversion of T4 to the more potent T3 and also the inactivation of T4 by conversion to reverse T3 (rT3) or inactivating T3 via conversion to T2. DIO1 is considered primarily to serve a systemic regulatory role, maintaining the appropriate T3/T4 ratio in the plasma and scavenging iodine from sulfated hormone for clearance in either bile or urine. DIO2 on the other hand is most abundant in the

brain, pituitary, thyroid, brown adipose tissue (BAT), and skeletal muscles. DIO2 acts as an outer ring deiodinase catalyzing the conversion of T4 to T3; thus, it is considered the primary activating enzyme. In contrast, DIO3 is primarily responsible for inactivation of various forms of thyroid hormone via inner ring deiodination. DIO3 is abundant in skin and vascular tissue, but is also found in the brain, pituitary, and other tissues. DIO3 also plays a key role in the placenta in protecting the developing fetus from excessive maternal thyroid hormones that might interfere with development. Together DIO2 and DIO3 act locally to control cellular exposure to T3 and thus thyroid signaling. All three deiodinases have been shown to vary both over the course of ontogeny but also seasonally, particularly in seasonally breeding animals.

### Receptors

Ultimately, thyroid hormone signaling is mediated by the binding of predominately T3 to nuclear receptors that regulate gene transcription. There are three isoforms of THR: THR $\alpha$ , THR $\beta$ , and THR $\beta$ 2, which form heterodimers with retinoid X receptors ( $\alpha$  and  $\gamma$  isoforms) to bind thyroid-response elements in the DNA. As with many nuclear receptors, the hormone binds to the receptor, which then translocates to the nucleus and binds to a thyroid-response element activating transcription of the target gene. However, evidence has emerged suggesting that unbound receptor complexes may bind to response elements independent of the hormone. In these cases, the unbound receptor may either suppress or activate transcription, with ligand binding leading to the opposite effect (Mullur et al. 2014). Further complicating the picture is the interaction of thyroid receptors with multiple corepressor and coactivator systems, which respond to a variety of signals including, but not limited to, nutritional and adrenergic signals. In addition to the traditional genomic receptors, non-genomic thyroid signaling pathways have been found by both in vitro and in vivo studies. In particular, the transmembrane protein integrin  $\alpha$ v $\beta$ 3 has two thyroid-binding sites, one that preferentially binds T3 and the other T4, with

differential output depending upon the ligand that is bound. Thyroid hormones have also been identified acting in multiple phosphorylation pathways.

### **Actions of Thyroid Hormones Across Vertebrates**

Thyroid hormones have been long considered to be a “slow” hormone often acting in a permissive manner. Traditionally, they are most closely associated with ontogenetic development, metamorphosis, general growth, and regulation of metabolic function. Disruption of proper thyroid function is also associated with a number of disease processes across vertebrate taxa.

Thyroid hormone action has been tied to development of the brain, sensory, skeletal, muscle, and other organ systems. These effects are mediated not only through genomic receptors altering gene expression, but also through modulation of kinase signaling pathways. In keeping with regulation of developmental programs, thyroid hormone signaling has been established as the sole signal necessary to trigger the metamorphosis from tadpole to adult in amphibians.

Apart from their major role in development and metamorphic processes, thyroid hormones are major regulators of metabolism. Thyroid signaling has been tied to regulation of basal metabolic rate, cholesterol synthesis, lipolysis, gluconeogenesis, cellular ion gradients, and insulin production. These actions are mediated through both genomic and nongenomic thyroid action involving numerous corepressor, coactivators, and varying receptor isoforms, and cross talk with other regulatory systems that are beyond the scope of this work, but see Mullur et al. (2014) for in-depth review.

Thyroid hormones are also tied to adaptive thermogenesis, as is supported by the observation that hypothyroid humans and animals readily develop hypothermia in response to cold exposure, while hyperthyroid individuals typically maintain elevated body temperature. Adaptive nonshivering thermogenesis in rodent models has been tied to BAT and specifically expression of uncoupling protein (UCP) 1, which is locally regulated by T3 following conversion from T4 by DIO2.

### **Thyroid Hormones as Regulators of Seasonality**

Thyroid hormones have recently emerged as potent regulators of seasonality. In particular, thyroid hormones have been identified as key regulators of seasonal breeding in both birds and mammals (Dawson 2002). Upregulation of TSH production in the pars tuberalis of the hypothalamus in response to daylength cues acting through TSH leads to increased DIO2 expression within the hypothalamic tanycytes, resulting in local T3 signaling that triggers the release of gonadotropin-releasing hormone (GnRH) which starts a well-characterized hormonal cascade, responsible for the regulation of breeding (Yoshimura 2010). Thyroid hormones have also been shown to be necessary for the expression of vernal migration (Pérez et al. 2016) and molt (Voitkevich 1966) in birds, but molecular mechanisms of action remain largely unknown for these and other seasonal processes.

### **Conclusion**

Highly conserved and pleiotropic in their function, the thyroid gland and its products are critical regulators of a wide array of processes, with more continuing to be identified. Despite a robust understanding of their molecular actions, particularly with regards to development, metabolism, thermogenesis, and disease processes in humans and other mammalian systems, much less is known regarding these processes in nonmodel systems.

## **Adrenal Gland: Glucocorticoids**

### **Introduction**

The adrenal gland is one of the major endocrine glands located on the posterior wall of the abdominal cavity and sites on the superior aspect of the kidney as its name would suggest. The adrenal gland contains steroidogenic enzymes responsible for the synthesis of numerous hormones including aldosterone, dehydroepiandrosterone (DHEA), cortisol, and corticosterone. Furthermore, they are also responsible for the synthesis of the catecholamines, epinephrine, and adrenaline as well

as small quantities of norepinephrine and noradrenaline.

### Anatomy

The anatomy of the adrenal gland varies across taxa. Mammals typically have an adrenal gland that is composed of an outer cortex composed of three distinct layers with an inner medullary region. The three unique regions of the cortex moving from the outer most to inner most layers include zona glomerulosa, fasciculata, and reticularis. In other taxa such as birds, the same level of organization is not present and cells of the cortex are mixed with medullary cells. In fish, an organized adrenal is almost completely absent and instead adrenal cells are dispersed throughout the kidney tissue. Despite the lack of adrenal anatomical homology across taxa, the cells responsible for producing each of the mineralocorticoids, glucocorticoids, and sex steroids are present in all taxa.

Each of three zones expresses a unique set of steroidogenic enzymes that are responsible for the production of various steroids. The zona glomerulosa produces mineralocorticoids such as aldosterone which plays a critical role in maintaining water balance by controlling the expression of sodium and potassium channels in the kidney. The zona reticularis produces DHEA, a weak androgen that is thought to regulate aggression during the nonbreeding season in many species. Finally, the zona fasciculata contains steroidogenic enzymes that control the production of glucocorticoids, cortisol, and corticosterone, which regulate the stress response. Additionally, the medullary region of the adrenal gland expresses chromaffin cells which are aptly named for the affinity for chromaffin dye and are responsible for the production of catecholamines, epinephrine/adrenaline, although norepinephrine/noradrenaline are also produced in small quantities. Epinephrine is released in response to the activation of the autonomic nervous system and has wide effects including increased heart rate, pupil dilation, slowed intestinal motility, etc. However, as this text is focused on behavior and cognition, the emphasis for the remainder of this section will be on the production of glucocorticoids and their major actions.

### Glucocorticoids

The major glucocorticoid secreted by the adrenal gland can either be corticosterone or cortisol depending on the species although the modes of action are identical. Corticosterone is the primary glucocorticoid in birds, rodents, and amphibians while cortisol is the primary glucocorticoid in primates, pinnipeds, fish, and whales. The difference in production is dependent upon the presence and abundance of key steroidogenic enzymes within the adrenal glands. As with all steroid hormones, glucocorticoids are derived from cholesterol either of dietary origin or synthesized *de novo* within cells. Cholesterol molecules are largely stored in lipid droplets within the steroidogenic cells of the adrenals. Final cortisol synthesis occurs in the zona fasciculata, while corticosterone is synthesized in the zona glomerulosa. In both cases, the steroidogenic enzymes responsible are found both in the intracellular spaces and within the mitochondria, where the final steps of synthesis occur. For both glucocorticoids, the final steps in synthesis involve conversion by 21-hydroxylase to an 11-deoxy form (either 11-deoxycortisol or 11-deoxycorticosterone) from either progesterone (corticosterone) or 17 $\alpha$ -hydroxyprogesterone. The 11-deoxycort is then converted by 11 $\beta$ -hydroxylase into its final form (Salway 1999). Since the final steroid products are lipophilic, they cannot be synthesized and stored like peptide hormones, but rather are immediately diffused into circulation.

### Central Regulation

As with thyroid hormones, production of glucocorticoids is centrally regulated by several key hormonal signaling cascades. Glucocorticoid synthesis is controlled by the hypothalamic–pituitary–adrenal (HPA) axis, which receives input on both metabolic and psychological stressors. The regulation of the HPA axis begins in the brain at the level of the hypothalamus as it integrates cognitive information from higher cortical regions such as amygdala and hippocampus, which provide information on feelings of fear, anger, stress, etc. and information on metabolic status from other nuclei within the

hypothalamus itself. Metabolic and psychological signals are integrated by the paraventricular nucleus of the hypothalamus, regulating the release of neuropeptide hormones. For most mammalian species, the PVN releases corticotropin-releasing hormone (CRH; 41 aa) and arginine vasopressin (AVP; 9 aa) into the portal vasculature of the median eminence where they travel to the anterior pituitary gland to interact with CRH and AVP receptors located on corticotrope cells. In birds, CRH is released in conjunction with arginine vasotocin (AVT) instead of AVP. Activation of corticotrope cells leads to the release of adrenocorticotrophic hormone (ACTH; 39 aa), which travels through the blood stream to the adrenal gland where it binds to melanocortin receptors primarily in the zona fasciculata. Activation of these receptors leads to the increased activity of steroidogenic acute regulatory (STAR) enzyme and side-chain cleavage enzyme activity, which are the two rate-limiting enzymes in steroid production. The activation of the HPA has a very weak stimulatory effect on the synthesis of sex steroids and mineralocorticoids. Synthesis of mineralocorticoids, such as aldosterone, is primarily under the control of the renin–angiotensin system.

### Carrier Proteins

Since steroid hormones are hydrophobic, they need to be transported in the blood and bound to carrier proteins. Carrier proteins allow for rapid transport of steroids through the blood stream. Cleavage by serpinase enzymes at the target tissues allow for rapid release of the hormone. The diversity of these proteins varies by species with many mammalian, reptilian, and amphibian species having sex steroid-specific binding proteins and multiple glucocorticoid-binding proteins, while birds have just a single glucocorticoid-binding globulin. Carrier proteins bind their preferred steroids with a high affinity but are considered low capacity when compared to the ability of other plasma proteins to bind steroids such as albumin. The presence of carrier proteins leads to the classification of hormones that are bound by the carrier protein which represent a majority of the steroid in circulation and steroids that are not bound by the carrier protein which are called

free. Much debate has focused on whether bound, free, or bound and free are responsible for the biological action of the steroid. Many theories have been put forth on the functional role of carrier proteins that is only starting to fully be understood with modern molecular techniques. The evidence today would suggest that glucocorticoid's ability to produce a biological response is mediated by both steroids that are bound by transport proteins and ones that are free in the plasma as well.

### Regulatory Enzymes

In addition to the production of steroid hormones by the adrenal glands and other tissue which perform *de novo* synthesis, steroid levels at the level of the tissue can also be rapidly modified. One of the major enzymes involved in corticosterone signaling is the enzyme 11 $\beta$ -hydroxysteroid dehydrogenase that can be found in two isoforms. 11 $\beta$ -hydroxysteroid dehydrogenases convert glucocorticoids into less active metabolites (11 $\beta$ -HSD2), while 11 $\beta$ -HSD1 performs the reverse reaction (Seckl and Chapman 1997). Expression of these enzymes allows for rapid regulation at the target tissue which can either increase or decrease the amount of steroids that are available to interact with either membrane-bound or nuclear receptors. Little is known about seasonal expression of these enzymes, but they play a critical role in regulating how much glucocorticoid actually encounters intracellular receptors in a cell (Seckl and Chapman 1997).

### Receptors

In birds and mammals, there are two intracellular genomic receptors that bind to corticosterone and less well studied membrane-bound receptors (Breuner and Orchinik 2009). The genomic mineralocorticoid receptor (MR, Type I) has a tenfold higher binding affinity for corticosterone than the genomic glucocorticoid receptor (GR, Type II). As for the membrane-bound receptors, genomic MR can be targeted for the cell membrane where it acts as a membrane-bound receptor and there is also a unique membrane-bound glucocorticoid receptor (Joëls et al. 2008). Insertion of the nuclear MR in the membrane results in a tenfold

reduction in receptor affinity for glucocorticoids and thus has similar binding characteristics as GR. Membrane-bound receptors act through second messenger systems to promote rapid changes in cell activity. This difference in binding affinity is thought to create a two-tier system for responding to basal and stress-induced levels of corticosterone with negative feedback mediated by receptors according to ligand affinity (de Kloet et al. 1998). Nuclear membranes can be found in the cytosol bound to heat-shock proteins (HSP). Once the glucocorticoids bind to the receptor, HSP dissociate which allows for translocation into the nucleus of the cell. Both genomic receptors are transcriptional factors with a zinc finger motif that bind to their respective glucocorticoid-responsive elements to influence gene transcription (de Kloet et al. 1998).

### Major Roles

Glucocorticoids are named after their first discovered function, which is to raise plasma levels of glucose by increasing gluconeogenesis. In addition, glucocorticoid hormones have been termed stress hormones because of their role in helping animals cope with stressful events and are activated at the same time as the flight or fight response by the autonomic nervous system (de Kloet et al. 1998). Physiologists tend to study circulating levels during basal conditions which are thought to reflect levels in an undisturbed animal. At basal levels, glucocorticoids are largely thought to be involved in regulating metabolism. Physiologists are also interested in how glucocorticoid concentrations change in response to stressors such as handling, captivity, predation, weather events, etc., which reflect concentrations that are much higher than basal concentrations and are often called stress-induced or peak glucocorticoids. Stress-induced levels of glucocorticoids are thought to play a different role than baseline levels helping the animal cope with the stressor by inducing drastic changes in physiology and behavior (Krause et al. 2016).

The role of hypothalamic–pituitary–adrenal (HPA) axis is to modify vertebrate behavior and physiology in response to unpredictable events (Sapolsky et al. 2000). Physiological changes must occur for an individual to survive in

conditions that are beyond those normally experienced (Boonstra 2004; Wingfield et al. 2015). Glucocorticoids are often thought to regulate overall energetic expenditures during stressors by reducing the activity of certain systems such as digestion, reproduction, etc., so that greater energy can be devoted toward systems required for immediate survival such as the skeletal muscle system. Thus, scientists have proposed that the activity of the HPA axis is linked with making important life history tradeoff decisions. For instance, when environmental conditions become sufficiently harsh that reproduction must be abandoned in order to save one's self at the cost of losing both one's self and their offspring, either baseline or stress-induced corticosterone levels are elevated (Krause et al. 2016). The actions of glucocorticoids on life history decisions are likely best studied in birds because of the ease at which parents and offspring can be monitored to see when critical points are reached that necessitate nest abandonment. In many bird species, there appears to be a threshold at which corticosterone levels will trigger nest abandonment. Slight increases can be beneficial and have been shown to be positively correlated with reproductive success. The thought being that parents that work harder to provision their offspring likely have slightly higher corticosterone levels in order to help fuel metabolism (Ouyang et al. 2013).

During periods of stress and negative energy balance, rising corticosterone concentrations have been linked with protein catabolism (Fokidis et al. 2012), lipid mobilization (Landys et al. 2004), escape behavior (Breuner and Hahn 2003), hyperactivity in cages (Lynn et al. 2003), suppression of reproduction (Calisi et al. 2008), increased feeding activity (Astheimer et al. 1992; Fokidis et al. 2012), predator awareness (Jones et al. 2015), enhanced memory formation and consolidation, and enhanced immune function (Sapolsky et al. 2000), all of which are thought to promote survival. Each of these examples is a testament to how many systems can be affected by the actions of corticosterone.

Prolonged stressors can lead to situations in which animals are chronically stressed. On the acute, time scale activation of the HPA axis is beneficial for the organism and promotes changes

in physiology and behavior that are necessary for survival. However, prolonged activation of the system, as observed with chronic stress, can have pathological consequences such as reduced fecundity, mass loss, reduced immune function, redistribution of fat deposits, etc. Chronic stress often results in unusual and inconsistent patterns of HPA axis function from changes in baseline corticosterone concentrations, changes in the stress profile, and finally changes in the density of MR and GR receptors in the brain.

## Time-Place Learning

Maria Cristina Tello-Ramos  
Department of Biology, University of Nevada,  
Reno, Reno, NV, USA  
School of Biology, University of St Andrews,  
St Andrews, UK

## Definition

Time-place learning is the ability of animals to associate when and where an event has occurred.

## Introduction

The universe is made up of a lot of space and relative time and just like Einstein's theory of relativity, animals too, can combine space with time. This is useful since often in our world, important events happen periodically within a specific location and thus associating the time and place of an event will be beneficial for animals as they learn to predict biologically relevant events (i.e., food availability, possible mates, or the presence of predators). For example, in the mid 1990s, Wilkie and collaborators noticed that scavenging birds would arrive to Granville's Island Market in Vancouver, Canada, 1 to 2 hours before the people that would eat their daily lunches outside (Wilkie et al. 1996). The time of day and not the number of people at the market was the best predictor of the number of birds that would appear in the vicinity waiting for the leftover chips. The famous Galápagos marine iguanas (*Amblyrhynchus cristatus*) that Charles Darwin threw over and over again to the sea, also time their twice a day visits to the seashore to match the time when the tide is low and they can feed on the algae (Wikelski and Hau 1995). Individuals that were able to anticipate the low tides and arrived at the shore earlier survived, while the late comers died of hunger. This result suggests that there is indeed "no greater wisdom, than well to time the beginnings, and onsets, of things" (Francis Bacon as cited by Scott 1908). Furthermore, the ability to be at the right place and at the right time seems to be taxonomically wide spread as animals will travel and arrive from distant locations at the time and place when resources are predictably available (e.g., honeybees, *Apis mellifera*: Beling 1929; Wahl 1932; amakihi, *Loxops virens*: Kamil 1978; oystercatchers, kestrels, *Falco tinnunculus*: Rijnsdorp et al. 1981; *Haematopus ostralegus*: Daan and Koene 1981).

Field observations such as the above led cognitive ecologists to question what are the cognitive mechanisms that allow animals to learn when and where resources will be available. In 1990, Gallistel proposed that animals can automatically memorise the nature of an event, the time and the

place of such event into a single tripartite code (Gallistel 1990). The idea of a tripartite memory code, however, has not been fully supported by subsequent research.

### Different Types of Timing Mechanisms

In the laboratory, time-place learning studies typically involve animals being trained to receive a food reward in one place at a specific time of day and a food reward in another place at another time. In one of the first formal time-place learning experiments, garden warblers (*Sylvia borin*) were tested in a four room experimental chamber with a central living area. During the day, each room would be automatically unlocked at a specific time of day for three consecutive hours so that a bird could go in and out of that one room to access grains. Afterwards, that room would be locked and another room would become “available.” Every time a bird entered a room to access the food the bird’s entrance was also automatically recorded. The birds learned the time-place association as demonstrated by birds anticipating which room would become unlocked next and by probe test sessions when all rooms were unlocked but the birds continued to enter the correct room at the correct time of day (Biebach et al. 1989). That the birds were using circadian information (or phase timing) to time their visits to the different rooms was confirmed when the birds’ performance dropped after a couple of days of the light-dark schedule being changed to a continuous 24 h lights-on schedule. Nevertheless, further manipulations showed that some birds were also using ordinal timing to time their visits to the different rooms. An ordinal timing mechanism allows animals to predict events based on the order in which these occur (Carr and Wilkie 1997). For example, even if waking up, getting dress, and going to work might happen at different times of day on different days of the week, these events should always occur in the same order. In the case of the garden warblers, when the accesses to the rooms was blocked so that the birds were prevented from visiting any of the rooms for one of the 3 hours sessions,

five out of nine birds visited the room that would have been next in normal visiting order rather than the room that was to be accessible according to the time of day. This meant that some birds were using different types of timing mechanisms to solve the task. A third timing mechanism has been distinguished as interval timing where animals can learn the duration of an event or the fixed amount of time between two events (Carr and Wilkie 1997). Interval timing is thought to be in use only when animals are presented with events ranging from milliseconds to hours in duration, not for events that happen once a day.

### Variation in Time-Place Learning

When the same protocol as the one used to test the ability of garden warblers to learn a time-place association was used to test different species of birds, there seemed to be variation in the details of what different animals were learning about the task. While both insectivorous black-necked weaverbirds, *Ploceus bicolor*, and the closely related granivorous fire-crowned bishops, *Euplectes hordeaceus* learned to visit four different rooms at four different times of day, only the insectivorous birds were able to shift their visits to the correct place in accordance to different time manipulations (Falk et al. 1992). It is possible that the degree to which time information is relevant to these two species is different. Since insectivorous birds feed from a resource that is limited to a certain time of day, time information is more relevant to their daily foraging routine. The granivorous birds, however, feed from a resource that is equally available throughout a day and thus, time information will be less salient to a granivorous bird than to an insectivorous one (Falk et al. 1992). Fish, for instance, really struggle to correctly time their visits to all four corners of a tank. Only when the task is made simpler by only rewarding two locations of a tank and fish had 3–4 weeks of training, did golden shiners (*Notemigonus crysoleucas*) were able to search for food at the correct side of the tank at the correct time of day (Reebs 1996).

Variation is useful because it can inform us about which ecological factors have contributed to the selection of specific cognitive abilities. In this case, time-place learning can thus be an example of adaptive specialization. This means that species that feed from resources that are restricted to a certain time of day or are available periodically are expected to be better at time-place learning than species that feed from resources that are constantly available. This has been further evidenced by comparing ant species. While the nectar-feeding ants *Paraponera calvata* were able to learn multiple locations where nectar would be provided at different times of the day with only five consecutive days of exposure (Harrison and Breed 1987), 14 other species of European ants that do not feed on nectar did not show any evidence of time-place learning (Dobrzański 1956).

### Time-Place Learning in Wild Animals

Other nectarivorous animals should also learn a time-place association readily since flowers are constant in space and will refill with time. This was proven to be true when the original garden warbler study was adapted to test the time-place learning abilities of wild, free-living rufous hummingbirds (*Selasphorus rufus*). Within only 1 day of training, six out of eight birds learned to visit four different patches of flowers at four different times of the day (from 8 to 9 am, from 9 to 10 am, and so forth) (Tello-Ramos et al. 2015). Even though most of their first visits to the array of four patches were directed to the correct patch at the correct time, the birds did not anticipate the shift (Fig. 1). Instead, birds needed to visit an empty flower on the previously rewarded patch to then directly switch their visits to the new rewarded patch. When the first 3 hours of a session were skipped and the patches were only presented during the fourth hour, the hummingbirds were equally likely to visit any of the four patches, showing no preference for using either a circadian or an ordinal timing mechanism. It was expected that if hummingbirds were using circadian timing, they would have mostly visited the fourth patch, which was the correct patch to

visit at that time of day. If instead hummingbirds had used ordinal timing, then they should have visited the first patch first, regardless of the time of day. It would seem that, unlike the garden warblers, hummingbirds needed both the time of day and the order or events to be able to accurately time their visits to the different patches. Needing to combine two types of timing information may also explain how rats learn the interval for which several different levers provide food whereby the expiration of an internal timer for the first lever could serve as the cue that starts the timer for the second lever and so on (Thorpe and Wilkie 2002).

### Conclusion

While spatial processing and its neural basis in the hippocampus (or the mushroom bodies in the invertebrate brain) are well understood in birds and mammals, time processing has been more elusive. In part because as explained above, there are different ways in which animals can tell the time. As suggested by Serry and Schacter (1987), different memory systems, or in this case timing mechanisms, may have evolved because some characteristics that make one timing mechanism efficient are incompatible with the performance of the other mechanism. Recent studies have shown, however, that at least in the mammalian brain the hippocampus is also responsible for organizing events in a sequential order (Eichenbaum 2013), giving at least the neural basis for ordinal timing.

Animals, in the laboratory and in the wild, are able to associate the time and the place of an event. What is not clear yet is why some species seem to use different types of timing mechanisms to solve the same task or why some animals combine two different types of timing mechanisms. It is possible that when remembering an event, animals instead of remembering a single tripartite code, animals remember separate information about the event in an episodic-like memory (what-where-when) (Clayton et al. 2001) and that the “when” can be encoded using different timing mechanisms depending on which is more

**Time-Place Learning,**

**Fig. 1** A four panel graph representing the percentage of first visits made to each patch over 5 days by eight free-living hummingbirds (mean). Each panel shows the visits made to each of the patches over 4 hours. From top to bottom, the top panel represents the visits to the first patch, the second panel represents the visits to the second patch and so forth. The horizontal black bars represent the hour when the flowers in that patch contained reward. The vertical dash lines indicate the times at which a patch became empty and the next patch contained reward. (Modified from Tello-Ramos et al. 2015)

relevant or salient during the event. This is further supported by animals remembering the location, the nature of the events, or the time of the event to different degrees making more or less mistakes when different types of information are put in

conflict (Marshall et al. 2013). Using standard but adaptable protocols to test and compare the time-place learning abilities that wild and laboratory animals have will help us understand the variation in this cognitive ability.

## Tip-of-the-Tongue Phenomenon

Evan T. Curtis  
Booth University College, Winnipeg, MB,  
Canada

## Definition

Tip-of-the-tongue is a state in which one cannot currently recall information from memory but believes that one will be able to recall that information in the near future.

## Introduction

If one is asked a question such as “what is the name of the place bees are raised for honey

production?”, one might either know that the answer is “apiary” or not know the appropriate term. However, there is a third possibility. One may feel as though one knows the answer but cannot quite recall it at the time. This phenomenon is known as a “tip-of-the-tongue” state, a memory state in which an inability to retrieve specific information is accompanied by confidence that the information will be retrieved later. The phenomenon was described in the early periods of psychological research (James 1893). However, Brown and McNeill (1966) were the first to bring the phenomenon under close empirical examination.

## Classic Paradigm

In the standard tip-of-the-tongue (TOT) paradigm, participants are given the definitions of relatively uncommon (low-frequency) words (e.g., apiary, nepotism, ambergris, pagoda) and asked to provide the words in question. Participants were instructed to do nothing if they either knew the word, were sure they did not know the word, or thought they might know the word. If participants instead were certain they knew the word but could not currently recall it, they were said to be in a TOT state. When in a TOT state, participants were asked to provide information about the word. Participants in a TOT state are often able to recall specific aspects of the word, including the number of syllables, the stress pattern of the syllables, the first letter of the word, words with similar phonology, and words with similar meaning. Participants are more likely to eventually recall the word when they are able to recall more of this partial information (Brown 1991; Brown and McNeill 1966).

## Factors Associated with TOT States

A number of factors predict the likelihood of entering a TOT state. These factors can be divided into factors associated with the participant and factors associated with the experiment.

## Participant Factors

TOT states become more common as participants age, with a more rapid increase in the very old (i.e., over 80 years old; Heine et al. 1999). Older adults are generally able to recall less partial information, including phonological information (e.g., syllabic stress) and semantic information (e.g., words with similar meaning). However, given sufficient time, older adults are as likely as young adults to eventually resolve the TOT state and recall the correct information. Observations of the change in TOT states across different ages have informed research on the neural basis of the TOT phenomenon (covered below).

Bilingual participants typically experience more frequent TOT states than monolingual participants, even if the bilingual participants are tested in their dominant language (Gollan et al. 2005). However, the difference is not consistent across all types of words. For example, bilingual and monolingual participants experience the same number of TOT states when recalling proper nouns (i.e., names) from a description. This pattern suggests that TOT states are exacerbated when multiple word forms (e.g., “hello” and “bonjour”) are associated with the same meaning (e.g., a common greeting).

## Experimental Factors

The characteristics of the information to be recalled have a clear influence on TOT states. For example, definitions of very common (high-frequency) words (e.g., dog, table, house) are unlikely to elicit TOT states simply because the information is easy to retrieve. Relatedly, the age at which a word is learned influences the likelihood of a TOT state (Navarrete et al. 2015). Words learned early are less likely to elicit a TOT state, and age of learning is often a better predictor than measures of word frequency. Additionally, experimental factors can temporarily change a word’s ability to elicit a TOT state. Recent exposure to phonologically similar words (i.e., priming) reduces the likelihood of a TOT state (Rastle and Burke 1996).

## Neural Basis of the TOT Phenomenon

A variety of brain structures have been associated with TOT states. TOT states are typically

accompanied by increased activity in the anterior and posterior cingulate cortex, multiple areas in the frontal and prefrontal cortex, the supra-marginal gyrus, the superior temporal gyrus, the supplementary motor area, and the insular cortex. The exact role of each brain structure is not currently well understood, but it is clear that TOT states involve the coordination of many different neural processes.

## Explanations of the TOT Phenomenon

There are two competing explanations for the occurrence of a TOT state: *direct-access* views and *inferential* views (Schwartz 1999). The direct-access view explains TOT states as a problem with the retrieval process, whereas the inferential view explains TOT states as a metacognitive judgment.

According to the direct-access view, the participant is unable to properly retrieve the correct information but is able to retrieve related or partial information. There are a number of different hypotheses specifying the exact locus of the retrieval deficit. The *blocking hypothesis* claims that, given a word definition, the participant retrieves an incorrect but related word. Retrieval of the related word then prevents retrieval of the correct word (i.e., retrieval is blocked). The *incomplete activation hypothesis* claims that the correct information is partially activated in memory. That partial activation is sufficient to produce a sensation of retrievability but insufficient to produce full retrieval. Finally, the *transmission deficit hypothesis* claims that the participant is able to activate semantic information from the word definition but that activation does not spread sufficiently to activate and retrieve the corresponding phonological information. All direct-access views are supported by the fact that TOT states are often resolved, that unrecalled words are better recognized in subsequent testing, and that participants can often recall partial information. The transmission deficit hypothesis in particular is supported by the fact that phonological (but not semantic) priming reduces the occurrence of TOT states.

In contrast, the inferential view claims that TOT states emerge from a metacognitive judgment based on a set of clues during retrieval. The inferential view consists of two hypotheses that differ in the nature of those clues. The *cue familiarity hypothesis* claims that participants make a metacognitive judgment based on how well they recognize the cue (i.e., the definition in the classic paradigm). Given familiarity with the definition, the participant infers that she must have learned the definition at some point and, as a result, must know the appropriate word. The *accessibility heuristic hypothesis* claims that participants make a metacognitive judgment based instead on retrieved partial information. Given the ability to retrieve **some** information, the participant infers that she must know the remaining information as well. The inferential view is supported by the fact that providing additional cue information can increase the likelihood of a TOT state without increasing later recall or recognition performance.

Although the direct-access and inferential views have traditionally been held in opposition, Schwartz and Metcalfe (2011) more recently proposed a synthesis of the two explanations. By their conceptualization, retrieval mechanisms explain the failure to recall the correct information (i.e., a direct-access explanation). From that failure, metacognitive mechanisms explain the experience of the TOT state (i.e., an inferential explanation). Thus each perspective might explain unique components of TOT states rather than being opposing and mutually exclusive views.

## Conclusion

TOT states involve a combination of (1) failure to retrieve complete information from memory and (2) a judgment that the information will be retrieved in the near future. TOT states are influenced by a number of internal and external factors. There are two primary competing explanations of TOT states, one framed in retrieval processes and another framed in metacognitive approaches. It seems likely that TOT states reflect a combination of both and draw on a variety of cognitive and neural mechanisms working in concert.

## Todd Shackelford

Farnaz Kaighobadi

Department of Social Sciences, Bronx

Community College, City University New York,  
Bronx, NY, USA

Todd K. Shackelford, Ph.D. is Distinguished Professor and Chair of the Department of Psychology, and Codirector of the Evolutionary Psychology Lab, at Oakland University. He is also the Editor of *Evolutionary Psychology* and *Evolutionary Psychological Science*. He takes an evolutionary psychological perspective in studying human sexual psychology and behavior, with an emphasis on sexual conflict between men and women.

## Early Life and Education

Todd Shackelford was born in Tulsa, Oklahoma in 1971. He attended public school during elementary, middle, and the first 2 years of high school. As a young man in high school, he aspired to a career in Heavy Metal music and under peer influence he missed school often and received poor grades. As a result, his parents pulled him out of public school and enrolled him in a private Catholic high school. The transfer and loss of contact with friends influenced him to channel his “teenage angst” towards education. He spent his final 2 years of high school focused on learning. Upon finishing high school in 1989, he secured a scholarship to attend the University of New Mexico. Little did he know that his move was a step into the heart of a fairly new field in psychology, evolutionary psychology, which he continued to pursue successfully until this day. During his undergraduate studies, Todd was especially inspired by and learned from

professors Steve Gangestad, Randy Thornhill, Hillard Kaplan, and Kim Hill. Determined to study evolutionary psychology in graduate school, he joined David Buss's lab at the University of Michigan, Department of Psychology in 1993. He then moved from Michigan to the University of Texas at Austin with David Buss's lab, where he completed his Ph.D. in evolutionary psychology in 1997. David Buss played a significant role in Todd's intellectual development, and in his personal and professional life; "I particularly respected his [David Buss's] remarkable work ethic and curious mind" (Shackelford, personal communication).

### Professional Career

After receiving his Ph.D., Todd began his academic career in 1997 as Assistant Professor in the Department of Psychology at Florida Atlantic University (FAU). In less than 10 years, he received tenure and was promoted to Full Professor. At FAU, Todd founded and chaired the Evolutionary Psychology program. He advised and chaired more than 20 graduate students' Masters and Doctoral theses. In 2010, Todd accepted an offer to chair the Department of Psychology at Oakland University and left South Florida for Oakland, Michigan. He left FAU for the opportunity to build graduate programs in psychology at Oakland University. As planned, in 2012, he founded and cochaired the Ph.D. and M.S. programs in psychology at Oakland University. Since then, the program has successfully graduated nearly a dozen Ph.D. students and over three dozen M.S. students. For his notable scholarship and dedication to the psychology department and development of students, in a few short years, Todd was appointed *Distinguished Professor* by the Oakland University Board of Trustees, on recommendation of the President and the Provost. Oakland University's Office of the Provost wrote on this accomplishment, "In six years, he [Todd Shackelford] has raised the University's international profile in the field of psychology. To support a growing student

enrollment, he recruited new faculty and developed Masters of Science and Doctor of Philosophy programs in the Department of Psychology, and attracted international scholars to interdisciplinary conferences on campus." Todd has been the recipient of numerous awards and honors by local, national, and international organizations for his substantial scientific contributions, outstanding teaching, and achievements in research. To mention a few, he was awarded Fellow status by the International Association for Research on Aggression in 2005 and by the Association for Psychological Science and the American Psychological Association in 2009 and 2011. Since 2015, he has served as Secretary/Archivist and Executive Council Member for the Human Behavior and Evolution Society. Currently, Todd is the Editor of *Evolutionary Psychology*, *Evolutionary Psychological Science*, Co-Editor-in-Chief of *Encyclopedia of Personality and Individual Differences* and *Encyclopedia of Evolutionary Psychological Science*, and Coeditor of *Springer Series in Evolutionary Psychology*. He has served on the Editorial Board of more than 30 peer-reviewed journals. He is the author and coauthor of around 300 peer-reviewed journal articles and book chapters and over 300 professional presentations. He has coedited 16 books. His work has been cited over 15,000 times.

### Research Interests

Todd's main research interest is on investigating sexual conflict between men and women from an evolutionary perspective including topics that address sperm competition in humans, romantic and sexual jealousy and infidelity, intimate partner violence and homicide, mate preferences and selection, and marital relationships.

Todd has made significant contributions to identifying and understanding evolved mechanisms for sperm competition in humans. Sperm competition occurs when a female copulates with and is inseminated by more than one male in a sufficiently brief period of time. Evidence for sperm competition in nonhuman species has

provided a framework with which to consider similar adaptations in humans. Todd and colleagues have addressed and provided evidence for psychological and behavioral adaptations in humans that were designed to solve ancestral problems of sperm competition. Todd and colleagues documented that as risk of sperm competition increases, men engage in more frequent mate retention behaviors, show more interest in in-pair copulation, engage in more frequent and shorter in-pair copulations, display copulatory urgency, and perform more semen-displacing behaviors. These findings have been reported in top-tier scholarly journals including *Evolution and Human Behavior*, *Human Nature*, *Journal of Comparative Psychology*, and *Journal of Research in Personality*.

Some of Todd's early research addressed the psychology of infidelity and romantic and sexual jealousy. Along with David Buss, he studied cues to infidelity and individual differences and relationship contexts that predict infidelity in long-term intimate and marital relationships. Furthermore, in a series of studies, Todd and colleagues investigated and provided evidence for sex differences in jealousy in response to the type of infidelity (sexual, emotional, or both), across cultures. Todd continued this work at FAU with his students, addressing emotional reactions to different types of infidelity and experiences of romantic and sexual jealousy among older adults.

Todd has made some of his most important contributions to understanding sexual conflict in humans in the area of intimate partner violence and homicide. With his students and colleagues, Todd has built a comprehensive model of men's violence against their female partners that includes both evolutionary, distal predictors as well as proximate, situational predictors of such violence. They have hypothesized that female-directed violence may be a form of mate retention behavior evolved to decrease the risk of female sexual infidelity and subsequent cuckoldry. The studies that followed documented perceived risk of infidelity to be a significant predictor of men's violence against female partners. More

specifically, Todd and students hypothesized that male sexual coercion and rape of an intimate partner are manifestations of male sexual jealousy, which may be a response to perceived risk of sperm competition. In two studies, they found that (1) men's sexual coercion correlated positively with women's past and future likelihood of engaging in sexual infidelity and (2) men who perform more mate-retention behaviors are more likely to perform sexually coercive behaviors against their partners. More recently, Todd and his students have investigated the role of life histories in predicting perpetration of intimate partner violence. Todd's research on intimate partner violence has been featured in numerous prestigious scholarly journals such as *Archives of Sexual Behavior*, *Journal of Comparative Psychology*, *Journal of Interpersonal Violence*, *Journal of Sex Research*, and *Violence and Victims*.

Taking an evolutionary psychological perspective Todd has extensively explored the psychology of mating, including mate value, mate preferences, and mate selection in humans. In a seminal research study, Todd investigated universal dimensions of mate preferences across 37 cultures. The study identified four universal dimensions and replicated previous research on sex differences in mate preferences, including women's greater valuation of social status and men's greater valuation of physical attractiveness. With David Buss and colleagues, he also conducted an impactful study documenting the cultural evolution of mate preferences among American college students over half a century.

Some of Todd's earliest and most important contributions were in addressing sexual conflict within marital relationships, including infidelity, marital conflict, marital satisfaction, spousal mate retention behaviors, spouse-killings, temporal stability of mate preferences and mate retention behaviors in marital relationships, and sperm competition in marital relationships. The findings from these studies have made significant contributions to understanding long-term mating in humans from an evolutionary psychological

perspective. Todd's work on marital relationships has been reported in top-tier scholarly journals including *Journal of Personality and Social Psychology*, *Journal of Research in Personality*, and *Journal of Social and Personal Relationships*.

From his expansive scientific research to his outstanding teaching and mentoring of future scientists, Todd Shackelford has made significant contributions to science, in general, and to the science of psychology, in particular. He has been a constant champion of the field of evolutionary psychology in his writings and his teaching. He has been an influential and inspiring mentor to his students, including this author, over the years. Todd has been as productive as ever in recent years. Currently, he is working on new research grants and exciting new research topics as well as several edited books, including *The Oxford Handbook of Evolutionary Perspectives on Religion*.

## Token

Amelie Romain

University of Strasbourg, Strasbourg, France  
Bureau d'étude AKONGO, Toulon, France

### Definition

Tokens are object or symbol that has no intrinsic value; its function is established through relations to other reinforcers. Tokens have been described as secondary reinforcer that can be exchanged for a primary reinforcer like food (Sousa and Matsuzawa 2001; Wolfe 1936).

### Introduction

Token systems are ubiquitous in human culture, providing the basic framework for economic transactions within the world. A token is often manipulable and easy to handle (e.g., coins, cubes) but can be non-manipulable as well (e.g., stimulus lamps, points on a counter, checkmarks). Tokens are called secondary reinforcers when they are collected and later exchanged for a primary reinforcer, as a meaningful object or some food. A primary reinforcer is an unconditioned or unlearned reward (e.g., food), whereas a secondary reinforcer is a conditioned reward associated with a specific value, which will be learned over time (e.g., money). Token's value can remain unchanged for extended period and, then, can be accumulated. Another property of token is to be used within a hierarchical system, where tokens of different values can exist (e.g., money) (Sousa and Matsuzawa 2001). In humans, from the supermarket to the stock market, any economic system of exchange involves some form of token reinforcement. In a token reinforcement system, the individual has first the possibility to obtain the token and, then, to exchange it, and this exchange response gives him access to the primary reinforcer. Tokens are often used in operant conditioning, a learning process through which the strength of behavior is modified by reward or punishment.

In humans, a token economy is a form of behavior modification designed to increase desirable behavior and decrease undesirable behavior with the use of tokens.

A token can be used to reinforce or elicit behavior but also to help to discriminate between tasks, depending on its relationship to the other events. These properties make tokens precious to study a large area of nonhuman animal behavior on cognition, such as the effectiveness of tokens as secondary reinforcements (Sousa and Matsuzawa 2001; Wolfe 1936), the use of tokens to request a specific food or tool, and numerical competence including numerous judgments, summations, quantity assessments, preference transitivity, delay of gratification, self-control, behavior inhibition, calculated reciprocity, prosociality, bartering, planning, and judgment biases such as endowment effect or loss aversion (Addessi et al. 2007, 2010a; Bräuer et al. 2009; Brosnan and Beran 2009; Cowles 1937; Dale et al. 2016; Dufour et al. 2009; Evans et al. 2010; Jackson and Hackenberg 1996; Lakshminaryanan et al. 2008; Massen et al. 2015; Sousa and Matsuzawa 2001; Wolfe 1936).

### Advantages of Token Use for Animal Cognition

Many studies have employed the paradigm of token exchange in experimental design to assess a variety of cognitive skills in nonhuman species, starting with great apes (Wolfe 1936). Since, most evidence suggests that primate species (Evans et al. 2010) but also ravens, pigeons (Jackson and Hackenberg 1996), parrots (Péron et al. 2013), rats (Cherot et al. 1996), and dogs (Ellson 1937) do learn to, at minimum, associate tokens with certain foods or certain task outcomes (Hackenberg 2009). Tokens are usually exchanged during distinct exchange periods, during which a specified exchange response involving the tokens is followed by presentation of some primary reinforcer (e.g., food) or other secondary reinforcers. Performances of these birds and mammals under schedules of food reinforcement suggest that tokens do indeed serve as conditioned

reinforcers. Token-reinforced behavior is also modulated, however, by the exchange production schedule that determines how and when exchange opportunities are made available. Numerous studies have shown that primates treat tokens as symbols that stand for those foods or outcomes (Addessi et al. 2007; Brosnan and Beran 2009). Thus, tokens can be used as tools to get a food reward but also be used in a novel discrimination task with token reward instead of direct food reward. In chimpanzees, tokens are almost equal to food rewards in their capacity to maintain and shape a discrimination behavior (Sousa and Matsuzawa 2001).

Token-exchange tasks can also be used in social learning paradigms. Typical studies in social learning used the two-action method, involving two physically distinct techniques to solve a single task. Although researchers attempt to design apparatus for which the two methods are of equal complexity, there is often an inherent bias whereby one method is simpler or more open to individual discovery (Hopper et al. 2011). Using distinguished token instead of distinguished methods might help to outreach this bias. Within this design, animals have the choice to animals to exchange one of two types of tokens for a different food reward: one type is associated with a highly preferred food and the other with a less preferred food. Individuals first observed a demonstrator from their group exchanges one of the two types of tokens to learn which token earned which kind of reward. Then, subjects are involved into an identical physical action, and it's only the token type that would give information to the preferences.

Token exchange inherently introduces an element of delay between behavior and reward. Thus, token-exchange paradigms are particularly relevant to better understand delay of gratification, behavioral inhibition, and self-control and are largely used in primate species (Evans et al. 2012). Self-control is defined as seeking to obtain a larger reward in the future over a smaller reward in the present. Different paradigms have been designing to modulate the complexity of the task. Judge and Essler (2013) use a token-exchange paradigm with two successive steps to test self-controlling capuchin monkeys. First,

animals were trained with a token that was associated with a lower-value food. When the monkey exchanged the token, the experimenter provided the monkey with a choice between the lower-value food item associated with the token and another token that was associated with a higher-value food. If the monkey chose the token, they could then exchange it for the higher-value food. On the contrary, some paradigms keep the food option visible. In that case, animals must inhibit the selection of immediately consumable food items in favor of selecting tokens that represented more preferred food items that could be consumed later. This experiment helps to assess whether primates – but potentially other species – can make decisions and evaluate task contexts in ways that go beyond making simple responses to prepotent and immediately available items such as food.

Delay of gratification, behavioral inhibition, and self-control are prerequisite for complex cognitive processes such as cooperation and planning. The multiple properties of tokens – they are exchangeable, they might be portable, and they can be accumulated and associated to different values – are combined when designing token-exchange tasks to assess these complex cognitive processes (Brosnan and Beran 2009). In a calculated reciprocity situation, partners must give something (e.g., a token, a service) with return expectancy. In addition to this return expectancy, the gift must occur intentionally from one partner to another, and each partner must know the value of the traded items. Several primate species have been tested in a token-exchange paradigm that seek to replicate these conditions. Primates were tested by pairs, but before starting testing, each individual has to learn the value of the different items, for themselves and for their partner. Individual A has been trained to exchange token A to receive food, whereas when exchanging token B, the individual did not receive food. Individual B has been trained in the opposite way: exchanging token B with the experimenter gives a food reward, but exchanging token A gives nothing. In the test condition, each of them possessed tokens valuable to their partner but useless to themselves. Primates could exchange with the experimenter at

any time. To receive food, individuals must first obtain the token from the other partner and then exchange it with the experimenter. Orangutans tested with this paradigm show calculated reciprocity (Dufour et al. 2009), whereas other great ape species tested and other monkeys failed to exchange (Pelé et al. 2009). Besides, these paradigms include several underlying tasks (e.g., interactions with the human partner, interactions with conspecifics, delay, number of token used) which help to give a better understanding of the cognitive process implied and, from a broader approach, the shared skills within primates.

Other complex social behaviors underlying by cognitive mechanisms, such as prosociality, voluntary actions that benefit others, might not be a uniquely human trait. Nonetheless, results in primates and other species are disparate, but few of the studies are methodologically comparable (Drayton and Santos 2014; Marshall-Pescini et al. 2016). To compare results across broader taxa, a token-exchange task paradigm frequently used with primates has been successfully applied to dogs (Dale et al. 2016). A comparative study has also been conducted on planning skills in ravens (Kabadayi and Osvath 2017) by using a similar methodology that used with primate species (Bourjade et al. 2014; Mulcahy and Call 2006; Osvath and Osvath 2008). Token-exchange procedures and tokens used as tools have been at the core on the design. Results indicate that ravens can plot for long-term gain at least as well as 4-year-old humans and some adult nonhuman great apes. Thus, by providing a common methodological context, token procedures are well suited to cross-species comparative studies, including humans, and whatever the degree of complexity of the cognitive processes involved.

Token-exchange paradigms are also highly relevant to behavioral economics. The use of tokens makes it possible for experimenters to control differences of currencies or the relative values of the goods to be exchanged. From an economic perspective, tokens can be conceptualized as a type of currency, earned and exchanged for other commodities. Token systems provide a controlled and analytically tractable environment in which to explore interactions between behavior and

economic variables (Hackenberg 2009). Token systems provide an alternate approach to the problem of common currency. Rather than defining currency in responses or time, the currency is defined in common token units, which make it possible for experimenters to normalize exchange parameters. Then, experimenters will be able to assess how much tokens a subject is willing to spend on an activity or commodity (Addessi et al. 2010). To the extent that tokens are interchangeable, one for another, they can be used to scale qualitatively different commodities. This approach leads to comparative cognition to assess different economic biases well-known in humans (e.g., loss aversion, endowment effect, framing effect, preference transitivity).

## Limitations of Token Tasks for Animals

Despite the potential of token-exchange tasks as a widely applicable test of animal cognition, there are some limitations which must be considered when designing tasks involving token-exchange paradigms and interpreting their results.

First, all these paradigms require an extensive training, which might be variable depending on the species considered but also between individuals (Brosnan and Beran 2009; Dale et al. 2016; Pelé et al. 2009). These approaches require as the minimum to create operational conditioned to make sure that animals associate token with a specific outcome. First, a schedule of reinforcement must be determined. Associate token as secondary reinforcers implies time and effort for staff training and management. In a general way, the human partner needs to have a relationship that involved only neutral or positive interactions with the animals, which might imply an enough amount of time; this is even more true if there is a need to insure predictability and that the human partner is associated with the exchange task for the animals (e.g., in planning task). It's important to ensure that the animals earn enough tokens in the early phases of the training so that it can exchange them for primary reinforcements regularly later. This leads to another limitation inherent to exchange tasks – only animals that reach the

predefined learning criterion will participate to the tests. Thus, results of exchange tasks can be biased toward animals capable of completing operant conditioning training. But this extensive training might also have an influence on behaviors observed during the test and thereby be a confounding factor on test results. When testing bartering in chimpanzees, authors reported that some behaviors have been shown uniquely after extensive training, chimpanzees engaged in accurate trade behavior as long as an experimenter enforced the structure of the interaction; however, trade between partners disappeared when this reinforcement was removed (Brosnan and Beran 2009). Finding a good balance between allowing animals enough experience to understand the mechanics of the task and avoiding overtraining the animals is an issue to treat carefully as both factors would impact the testing phase and in extenso the results.

The context of exchange paradigm can also influence. Whereas social learning paradigms using only tokens and not mechanical apparatus may elicit the discovery and the difficulty biases, authors reported that capuchins proved to be highly motivated and skillful token exchangers and when individually tested never displayed token exchange in the social context. But as noticed by the authors, these individuals were all low-ranking individuals, and similar behavior (i.e., not doing the task) may have been appeared with a classic apparatus. Nonetheless, all species cited (pigeons, parrots, ravens, rats, dogs, primates) have social structures, and social context has to be taken into account, even more particularly in complex tasks such as bartering, trading, and reciprocity (Marshall-Pescini et al. 2016). The social facilitation control is an extremely important condition to include to disentangle any differences between test and nonsocial control conditions.

When tokens are used as reinforced conditioners, several authors reported frequent instances of misbehavior, defined as an excess frequency of exchange responses (Addessi et al. 2010a; Defulio et al. 2014; Pelé et al. 2009). Some individuals did not exchange tokens more than

other items (e.g., stones, no-value token, etc.). Although exchanging no-value tokens or other items does not lead to a food reward, trading per se might be sufficient motivation for the animals to continue exchanging (Carpenter and Locke 1937). On the contrary, a decrease of motivation has been reported in capuchins (Addessi et al. 2010b), due to the delayed feedback associated to token exchange. Whereas they can easily learn to associate several types of tokens with different amounts or types of food, tokens are not dealt with in the same manner as the food for which they are exchanged. Tokens may also evoke or elicit behavior based on their temporal relations to food.

Such token-evoked behavior is probably more likely with manipulable tokens (e.g., cubes, coins) than with non-manipulable tokens (e.g., lights). Manipulable tokens are handled in several ways throughout the sequence of earning and exchanging them for food, and this physical contact with the tokens then becomes part of the behavior engendered by the procedures. Then, it may be desirable to use non-manipulable tokens, less susceptible to intrusions from embedded stimulus–food relations. Specific methodological choices therefore depend on the types of questions asked.

Token choice task might be more cognitively demanding compared to similar task. This argument can be made, for instance, in the case of prosociality, also investigated using the bar-pull paradigm (Marshall-Pescini et al. 2016). Studies using different paradigms sometimes lead to various conclusions, but few studies used the same methodology. In prosociality studies, dogs have been sensitive to rather subtle methodological changes – which might be the case for other species. This highlights the necessity to adopt a comparative approach with the most similar methodology possible when investigating cognitive skills across species.

## Conclusion

Token-exchange paradigms have been revealed as useful tool to explore many different cognitive skills, from numerical competence to prosociality.

Although the limitations must be considered when designing study, by providing a common methodological context, token procedures are well suited to cross-species comparative studies, particularly within birds and mammals. This approach allows for a more thorough evaluation of the biological and evolutionarily shared aspects of striking cognitive abilities across species.

Token-exchange paradigms are particularly promising to explore behavioral economics and cognitive bias in animals and should receive increase of attention in the near future.

## Definition

Tolerance is the decrease in the response to a determined amount of a drug. This effect may also be expressed as a necessity for increasing the dose of a drug to obtain the initial effect. Tolerance can be classified in two categories: acute tolerance and chronic tolerance. One key difference between them is that acute tolerance results from drug-compensatory processes elicited by the drug itself. In contrast, chronic tolerance is, at least in part, a result of learning mechanisms (i.e., Solomon and Corbit 1974; Siegel 2001).

Acute tolerance is the decrease in the response to a drug during a single administration. Drugs disrupt homeostasis of the organism, and to restore homeostasis the organism responds in an unconditioned or reflexive way to compensate for the drug-induced disruption. This unconditioned response constitutes acute tolerance. Consequently, the net result in behavior observed after drug administration is the summation of the primary change produced by the drug, and of the secondary compensatory responses (i.e., acute tolerance). This latter effect can be seen in isolation when the primary reaction produced by the drug is no longer present, for example, within a single administration of morphine the subject can develop acute tolerance, producing hyperalgesia. Then when morphine is metabolized and eliminated (and its analgesic effect ends) an increased sensitivity to painful stimuli is often observed, because the compensatory responses continue and therefore the sensitivity increase.

Chronic tolerance, on the other hand, is a decrease in the effect of the drug over the course of a series of administrations. Like acute

tolerance, chronic tolerance is generally thought to be mediated by compensatory responses; however, while acute tolerance is solidly understood as a consequence of drug-compensatory process provoked by the drug administration itself, diverse accounts have been provided to explain the psychological mechanisms underlying chronic tolerance.

## Mechanisms of Chronic Tolerance

Multiple models have been proposed to explain chronic tolerance. Considering that tolerance involves changes in behavior with repeated or chronic experience with a drug, these theories are in most cases based on theories of learning. One account is the opponent-process theory (Solomon and Corbit 1974). This theory assumes that when organisms react to stimuli, this reaction generates two processes that sum to influence behavior. The first, involves a direct response known as the *a-process* which is counteracted by a second, process, that acts in the opposite direction of the *a-process*, known as *b-process*. This *b-process* would constitute the compensatory response to the drug. In the case of ethanol consumption, the *a-process* is the effect of intake that, for example, could be the decrease in body temperature caused by administration of ethanol. The *b-process*, following the same example, would be an increase in body temperature. The model also included two more tenets: the *a-process* magnitude is maintained with the same dose of a drug; however, the *b-process* gets stronger with repeated intake of the drug (Baker and Tiffany 1985). Because of the strengthening of the *b-process* in each drug intake experience, subjects become more tolerant. That is, the compensatory responses become more effective to compensate the disturbance of the drug. In the example, this translates into maintaining the body temperature constant, reducing the hypothermic effect of ethanol.

One caveat of the model is that it cannot explain why sometimes chronic tolerance is observed and why sometimes it is not. More specifically, it cannot explain the situational specificity of drug tolerance, that is, why tolerance is observed only in the

presence of environmental and contextual cues that are related to drug administration.

A model based on associative learning postulated by Siegel (1975, 2001) states that chronic tolerance is at least partially the result of associations between the drug (or its effects on the organism) and cues present during administration or consumption. The internal disruption in homeostasis caused by the drug is considered an unconditioned stimulus (US), which causes the organism to emit an unconditioned response which maintains the homeostasis. The responses involved in acute tolerance constitute the unconditioned response in this model. The stimuli that are typically present at the time of drug administration signal the onset of the drug, and thus work as conditioned stimuli (CS). When the CSs are present they prepare the organism for the effect of the drug by allowing it to anticipate the homeostatic responses which compensate for the drug effects (i.e., conditioned compensatory response; CCR). This model, (e.g., Siegel 1975; Siegel et al. 2000) emphasizes the role of compensatory conditioned responses as the basis of drug tolerance: according to the model, these conditioned compensatory responses are the main cause behind the reduction in the effect of a drug (US). Furthermore, Siegel's model can also explain the occurrence of withdrawal symptoms. If the cues associated with a drug are present in the absence of its effect (i.e., with no consumption), the elicitation of compensatory responses would have nothing to compensate for and will produce an aversive motivational state. This phenomenon would be at least in part responsible for the manifestation of cravings (Siegel 2001).

Consider a subject who habitually drinks or takes a drug in a certain place regularly (e.g., a bar). In such a situation, the subject associates features of the place (e.g., physical settings, friends, vision of the drink, taste) with the effects of acute tolerance. This "bar context" elicits compensatory responses that prepare the individual for the effect of the drug. If one night the person exposes himself to the bar, but does not drink, in this situation, the compensatory responses would be elicited in absence of any drug perturbation to compensate, causing cravings. These cravings

will cease if the person consumes, as the drug would return the body to the original homeostatic state. If another night the same person goes to a new place, the compensatory responses will not manifest and the subject will not show tolerance after consumption and the full effect of the drug would be expressed.

Siegel's model of drug tolerance has received much empirical support. It helps explain the acquisition and development of drug tolerance, the manifestation of withdrawal symptoms, and the motivational aspects of drug abuse and dependence, while also contributing to the development of potential treatments from the perspective of Pavlovian conditioning. For example, following Pavlovian principles, researchers have focused on extinction learning as a Pavlovian model for cue exposure therapy (e.g., González et al. 2016), which can be used to decrease tolerance and withdrawal symptoms and thus help in removing some of the elements that maintain drug consumption (Siegel et al. 2000).

## Pharmacodynamics and Pharmacokinetics of Tolerance

At a pharmacodynamic level tolerance involves several processes that result in impaired excitation of the drug receptor. For example, a drug constantly binding with the receptor may desensitize it (Bespalov et al. 2016), reduce its receptor density in the neuron (Chavkin and Goldstein 1984), or trigger processes that modify the firing rate of the action potential (Allouche et al. 2014).

At a pharmacokinetic level (i.e., dispositional tolerance) tolerance involves processes that lead to a smaller amount of the substance at the site it affects. This may be caused by metabolism (e.g., a decrement in enzymes that make a drug active), absorption, distribution, and excretion of drugs.

## Compensatory Responses to Nondrug Stimuli

Conditioned compensatory responses involved in tolerance have been found in different types of drugs, including commonly abused drugs such as

opiates, ethanol, and caffeine. This process applies to drugs due to the disrupting effects of such stimuli, but also it applies to nonpharmacological stimuli that produce strong physiological reactions. In general, compensatory responses are present whenever the organism needs to adapt to new stimuli (Siegel 2008). For instance, compensatory responses to chromatic stimuli produce adaptation. Continued presentation of a color over a period of some minutes causes it to appear desaturated. The adaptation to color involves a chromatic CCR, analogous to those responsible for drug tolerance. For example, cues associated to a green color produce a perception of magenta when they are presented as achromatic test stimuli. This kind of CCR can also be seen in the adaptation to hypothermic stimulation, in which a reduction in the induced-coldness of the body is observed over the course of repeated applications of cold water. Similarly, signals associated to the immersion cause a CCR of hyperthermia. CCRs are involved in ingestion as well, for example, insulin is sometimes released in anticipation to food intake. Cues for the taste or smell of the food can trigger the release of insulin long before the food is ingested. This mechanism allows the organism to be prepared for the sugar arrival, allowing its adaptation. All these examples support tolerance as a mechanism that can be applied to several different situations. These situations include drug use, but also the reaction to different kind of stimulation, and consequently, it seems to be a general mechanism to adapt to disrupting stimuli.

## Tom Zentall

Rebecca Rayburn-Reeves  
Georgia Southern University – Armstrong  
Campus, Savannah, GA, USA

Thomas (Tom) Zentall is a Professor of Psychology at the University of Kentucky. Given over a half-century of contributions to the scientific community, he is arguably one of the most prolific and influential researchers in the fields of comparative cognition and animal behavior. From the time he began publishing in 1966, he has authored over 340 journal articles and book chapters, along with

editing seven books on topics related to social learning, animal intelligence, stimulus class formation, and decision making. Throughout his career, he has mentored over 30 students, aiding in their obtainment of a Master's or PhD degree. He has received over 20 grants from organizations such as the National Institute of Mental Health (NIMH), the National Science Foundation (NSF), the National Institute of Child Health and Human Development (NICHD), and Fulbright Scholarships, along with being honored numerous times for his contributions in the field of psychology from various associations to which he has offered his expertise in roles as Editor, Fellow, Associate Editor, and Consulting Editor. He is an elected Fellow for the Society of Experimental Psychology and has received awards as a Distinguished Researcher (CCS) and Lecturer (EPA), as well as Distinguished Contributions to Scientific and Basic Research (APA). He has also served as Chair of the Governing Board of the Psychonomic Society, and as President of the American Psychological Association (APA, Divisions 3 and 6), Midwestern Psychological Association (MPA), Eastern Psychological Association (EPA), and Comparative Cognition Society (CCS).

Tom's extensive knowledge and experience in the field of animal behavior, combined with his personal belief in the importance of investigating the links between human and nonhuman animal cognition, has resulted in the advancement in our understanding of both the unique and shared abilities of humans and our nonhuman relatives. Interestingly, Tom did not start out knowing he wanted to study psychology. It was the recognition of a serendipitous finding and a keen determination to "...go where the questions lead you" (Interview with Tom Zentall 2014) that led Tom down the road of comparative cognition and animal behavior.

Tom was born in Beziers, Southern France, in 1940 during the Second World War. His family came to the United States in 1942 and settled in New York City. He attended Brooklyn Technical High School and went on to major in Electrical Engineering at Union College in Schenectady, New York. While in pursuit of this degree, he took psychology classes where he learned about the various experiments conducted with human

and nonhuman animals. His interest in psychology grew as he realized he wanted to apply scientific principles to the field of psychology. He recognized that this was already happening through the work of others, such as B. F. Skinner and Jean Piaget, who sought to create systematic ways of creating sound experimental designs to the study of animal and human behavior. However, he also found that many experiments lacked the proper controls needed to parcel out the meaning behind the data. Additionally, he was influenced by the importance of interpreting results in more parsimonious, objective ways as compared with much of the research at the time that sought more cognitive and abstract explanations for the behaviors observed.

After obtaining both a Bachelor of Science in Psychology and a Bachelor of Electrical Engineering at Union College, Tom began his doctoral training under the tutelage of Donald (Al) Riley at the University of California, Berkeley, in 1963. At the time, Al was working with human children and adults looking at various forms of generalization across physical dimensions. In an interview with Jeff Katz at the 2014 Comparative Cognition Conference, Tom stated that working with these populations was rather difficult because of the inherent complications that arise from dealing with children (Interview with Tom Zentall 2014). Both Tom and Al were interested in generalization gradients, which are measures of the level of activation to a set of stimuli that lie along a single physical dimension, such as color or brightness. In humans, activation of the color red, for example, produces a systematic activation of various shades of red around a gradient, with colors more similar to the original stimulus producing higher activation than those further away. Wondering whether a similar phenomenon occurs in animals, Tom and Al investigated this with Japanese quail, rearing them with monochromatic light and later testing them on variations of light gradients. They found that the same basic generalization gradients were generated in the quail as had been previously observed in humans, suggesting that this must be a process that is built-in to many organisms with similar physiological structures. Tom quickly realized the

benefit in working with animals, such as quail, who are precocious, easy to raise and handle, and will work hard for very little food. From this initial line of research, Tom would begin building his legacy.

After working at the University of Pittsburg for 6 years, Tom took an Assistant Professor position at the University of Kentucky in Lexington where he remains as productive today as when he started. He began his research working with pigeons. Like quail, pigeons are relatively easy to maintain and will readily work for small payouts, such as food. They are also a species on which much of the previous research in animal behavior had been conducted. His initial interests were in memory strategies and concept learning in human and non-human animals. Tom began his experiments by replicating older research to see if the results were both accurate and reliable. He also figured out how to redo experiments in which he felt the proper controls or aspects of the methodology were not present. One of these lines of research dealt with the now famous matching-to-sample paradigm, where an animal is presented with an initial (sample) stimulus, such as a green light, and then given the option of two (comparison) stimuli, such as a red light and a green light. In order to receive food, the animal is required to peck at the key that matches the initial sample key, in this case, the green light. Although pigeons could readily learn the initial discriminations, when tested on the critical transfer trials in which they received a novel pair of stimuli, such as blue and yellow lights, responding fell to chance, suggesting they were not able to develop the concept of sameness (also called identity). Tom realized that the failure of pigeons to transfer this behavior to the novel stimuli had much to do with their natural tendency to avoid novelty, as pigeons are neophobic (Zentall and Hogan 1974, 1976, 1978; Zentall et al. 1981a, b), as well as the fact that, during training, pigeons appeared to avoid contact with the negative stimulus, thereby learning little about the incorrect associations. Therefore, he and his colleagues designed clever ways to train pigeons on multiple colors from the start of training, eliminating the element of novelty, as well as providing negative instance trials

where no comparison was correct, and found pigeons were successful in demonstrating a generalized matching-to-sample concept on test trials.

In a related line of research on delayed matching-to-sample, where there is a time delay between the offset of the sample stimulus and the onset of the comparison stimuli, Tom again realized that the rapid decline in accuracy over delay by pigeons was due to ambiguity in the methodological procedure, and not to the pigeon's inability to maintain the stimulus in memory over time (Zentall 1997, 1999). Here, Tom created a clear distinction between the intertrial interval, or the time between trials, and the delay between the sample and comparison stimuli (the time within trials) by using a house light to signal between-trial intervals. He was able to demonstrate that pigeons are adept at maintaining memory for recent stimuli far longer than was once believed. Therefore, one of the main lines of research Tom has pursued, which has contributed highly to the field of comparative cognition, is the use of proper methodological designs to reduce instructional ambiguity in order to ferret out the true nature of an animal's cognitive capacity.

Over the years, Tom has also investigated various lines of research that could fall under the category of parsimony in explanations related to the more cognitive explanations given in many articles on human behavior. One of the major contributions of Tom's work has been to show that results in the human literature that are often explained in more cognitive terms may be better explained through simpler, more basic processes, as nonhuman animals exhibit highly similar behavior under comparable circumstances. Some of the lines of his research under this umbrella deal with decision making, maladaptive behavior and "gambling," cognitive dissonance (versus contrast), imitation and social learning, and self-control. With the help of his graduate students, Tom has also been able to study other nonhuman animals, such as rats, quail, horses, and dogs, and has successfully contributed a wealth of knowledge on the abilities of these animals to solve various cognitive tasks. Tom's broad contributions to Comparative Cognition and Animal Behavior can best be classified through his

philosophy, pioneered by Edward Tolman, as a cognitive behaviorist; one who seeks to understand the cognitive nature of behavioral phenomenon through rigorous and sound methodological design. This approach to studying animal learning is apparent throughout Tom's many lines of research into the subtly powerful mixture of these very important aspects in psychology. As eloquently laid out in his paper "A Cognitive Approach to Animal Learning and Behavior," Tom argues for three fundamental aspects when conducting research: objectivity, parsimony, and serendipity (Zentall 2001). This paper in many ways exemplifies Tom's contributions to the field of comparative cognition and animal behavior. His work has undoubtedly helped to shape the foundation of behavioral research and comparative cognition in ways that will forever benefit this field and inspire young researchers to pursue these important and incredibly fascinating questions for decades to come.

response to a threat (Gallup 1974). Some writers used the term “feigning death” or “apparent death” because of its definite survival value as part of their defense mechanism in certain situation.

## Introduction

Currently, there are three hypotheses on how TI potentially increases survival chances of animals (reviewed in Rogers and Simpson 2014). First, fire-bellied toads (*Bombina* spp.) may escape from predator by “death” displays with additional chemical secretion as aposematic warning system. Second, insects such as pygmy grasshopper (Tetrigidae) were seen stretching out its body and causes it is hard to be eaten by predator. Thirdly, arthropods may use TI in enhancing camouflage mechanism by allowing them to fall away from predator as they typically live on vertical surfaces followed by a period of motionless.

## Definition

The term “tonic immobility” (TI) is often defined as a stage of animal to become temporarily immobile upon external stimulus. In physiologist perspective, this behavior referred as a temporary loss of muscle and/or neurological function in

## Advantages

TI in animals can be observed in sharks but believed to be related to mating behavior. Some scholars suggesting that male biting the female would immobilize and enable internal fertilization. Scientists have exploited TI in sharks as an aid when handling or tagging in the field to minimize struggling thus reducing the possibility of injury. Many anglers benefit from TI in removing hook from sharks, although caution should be taken as this phenomenon does not occur in all species of sharks.

## Inducing TI to Animals

Most other vertebrates, namely rabbits, guinea pig, chicken, and birds can also be induced to TI by human without causing any apparent stress to the animal by gently turning them upside down, i.e., dorsal side on a firm-flat surface and stroking a particular area. In sea turtle hatchlings, the response only can be induced by additionally closing their both eyes as a mean of deterring their visual cue and pressing on the plastron to

stabilize the body due to its curved carapace shape (Rusli et al. 2016). However, applying TI in adult sea turtles requires much simpler technique by only stroking their neck.

Animals in this natural state of paralysis can last for a few seconds to over several minutes. In recording TI on any particular animals, scientist usually record the period to the first major movements and termed as TI duration. The TI durations vary considerably interspecies (species-specific behavior) and to a lesser degree with individuals within a species. To date, some descriptive studies on individual variations in TI occurrence and duration have shown that it is affected by individual (e.g., prestimulation status and internal physiology) or environmental factors (e.g., lights and temperatures) (reviewed in Miyatake et al. 2004).

## Conclusion

In terms of animal cognition perspective, TI is known as an unlearned behavior and is believed to be inherited genetically from parents. In addition, the duration of TI can potentially evolve by natural selection process.

## Introduction

Tools and other utilitarian artifacts pervade humans' lives. They have played such a pivotal role in theories of human evolution that tool use has traditionally been considered a behavioral indicator of complex and flexible cognition. While this early promise has long triggered and maintained keen scientific interest for the study of tool use in nonhuman animals, it may also have revived some naïve anthropomorphic and even anthropocentric biases, particularly when studying species that are evolutionarily close to humans. It is noteworthy that not all cases of tool use necessarily imply high levels of cognitive sophistication, and we should not automatically attribute some of our psychological characteristics to other tool-using species, just because tools are part of our human identity. In fact, tool use is a broad functional category of behaviors that includes a wide range of actions directed to various objects, and whose cognitive substrates may differ substantially between species. Among the species-specific factors underlying the expression of tool use, ecological stimuli, social influences, psychological traits (e.g., cognitive processes and motivational determinants), and anatomical features differentially contribute to engaging in the use of objects as tools.

First, definitions of tool use – following a list of relatively consensual criteria – and description of some of its variants are provided. Then, the main ingredients that allow the expression of

tool use across taxonomic groups, distinguishing between extrinsic factors (e.g., stimuli from the physical and social environments) and intrinsic factors (e.g., psychological processes and anatomical features), are reviewed. Focusing on the proximate causes of tool use (i.e., mainly mechanisms) may help generate further inquiries about its ultimate consequences (i.e., its adaptive nature). Indeed, the challenges associated with longitudinal designs and correlational tests between tool use and individual fitness benefits make it extremely difficult to unequivocally demonstrate the adaptive value of tool use, as measured by increased survival rate and reproductive success.

Following the “design-feature argument,” in which the detailed structure of a given behavior is matched against the requirements of its hypothesized function, one way to circumvent the lack of evidence for the fitness-enhancing value of tool use is to conduct an in-depth structural analysis of this behavior. The heuristic power of the behavioral structure-function interface is reflected in the following statement by Pellis and Pellis (1998): “Therefore, behavioral description informs functional inference, which in turn, influences further description” (p. 115). For instance, kinematic and biomechanical analyses of patterns of grip and hand movement capabilities across different primate species are indicative of evolutionary scenarios about stone tool technology in ancestral hominins. By examining the role of ecological factors, social influences, cognitive processes, and motivational determinants in the development, expression, and evolution of tool use, we aim to show that this behavior, characterized by a patchy phylogenetic distribution, is not necessarily synonymous with highly complex intelligence and can be explained outside an anthropocentric framework.

## Defining Tool Use

About 60 years after Jane Goodall’s pioneering observations of a wild chimpanzee fashioning and using a stick to extract termites in Gombe, Tanzania, the debate around the appropriate characterization of the term “tool use” is still

open. Because the definitions of tool use range from a focus on the *goal* of the action (i.e., the functional consequences of the tool-assisted behavior patterns being performed), to the *means* of the action (i.e., the structural details of these behaviors), to the condition of the *object* employed, there is no universal consensus among researchers about what constitutes tool use and what constitutes (object-assisted) problem-solving. These differences in perspective stem from conceptually and methodologically divergent approaches across academic disciplines (e.g., ethology, psychology, and anthropology), and this situation is often referred to as the “tool use paradox.”

Arguably, one of the most widely adopted definitions of tool use was provided by Shumaker et al. (2011). With a focus on the *goal* of the action, tool use is defined as “the external employment of an unattached or manipulable attached environmental object to alter more efficiently the form, position, or condition of another object, another organism, or the user itself, when the user holds and directly manipulates the tool during or prior to use and is responsible for the proper and effective orientation of the tool” (Shumaker et al. 2011, p. 5). With a focus on different functional features of a tool, alternative definitions consider tool use a form of problem-solving that includes the instrumental use of an object (e.g., St Amant and Horton 2008). For example, according to Shumaker et al. (2011), a weighting scale cannot be categorized as a tool because this object does not alter the form, the position, or the condition of another object or the user. However, under St. Amant and Horton’s (St Amant and Horton 2008) functional definition, using a weighting scale to detect an object’s weight is a way to mediate the flow of information, and as such, it is a form of tool use.

Another criterion for tool use focuses on the condition of the utilized *object*. The same object may be either freely manipulable or attached to a substrate, which potentially affects its action-mediated use. For many authors, a Californian sea otter pounding a stone onto a shellfish to break it open is an example of tool use, whereas a wrasse pounding a shellfish onto a rock to crack

it open is not. Clearly, those behavior patterns (i.e., the pounding actions) are structurally similar, but because the rock used by the wrasse is attached to a substrate (i.e., the ocean floor), they are put into separate functional categories by Shumaker et al. (2011). In line with this argument, “true tool-using” avian species (following the definition by Shumaker et al. 2011; e.g., an Egyptian vulture breaking open an egg by dropping a stone on it) have larger residual brain sizes (regressed against body weight) than bird species using attached objects that do not qualify as tools (e.g., a sea gull dropping an egg on a seashore boulder; Lefebvre et al. 2002).

However, some researchers have disagreed about how structurally similar object-assisted actions may be characterized as being functionally so different. By focusing on the biomechanics of tool use, their approach proposes an embodied theory that shifts the focus of study from the object (i.e., the tool) or the goal to the *action* (i.e., “to tool” as a verb; Frigaszy and Mangalam 2018). “Tooling is deliberately producing a mechanical effect upon a target object/surface by first grasping an object, thus transforming the body into the body-plus-object system, and then using the body-plus-object system to manage (at least one) spatial relation(s) between a grasped object and a target object/surface, creating a mechanical interface between the two” (Frigaszy and Mangalam 2018, p. 194). Behaviors that have been historically recognized as tool use, such as a chimpanzee climbing on top of a pile of wooden boxes to reach for a hanging banana, do not qualify as tooling, because the tool has to be grasped (with the hand or the mouth). In a slightly different view, although partly supporting this action-based approach, some researchers argue that this embodied theory of tool use downplays the role of cognitive processes underlying these object-assisted actions. They claim that tool use is not only about manipulating an object to achieve a goal but also about understanding the action-relevant physical properties of this object in the context of achieving this goal (i.e., embodied cognition; Osiurak et al. 2010). In fact, human patients with a left brain-damaged condition that results in an impairment

of coordinated movements associated with tool use attempt to perform daily actions using inappropriate tools or display inappropriate actions with everyday tools (e.g., trying to cut a tomato with a comb or rubbing a hammer on a nail instead of pounding). Consistent with our initial objective to dissociate ourselves from the anthropocentric views that have pervaded tool use research in the past decades, we adhere to the action-based approach proposed by Frigaszy and Mangalam (2018), as this may further our understanding of the causal mechanisms underlying the expression of tool use within and across species.

## Different Forms of Tool Use

Even though the behavioral specializations broadly acknowledged as tool use are sporadic in their phylogenetic distribution and relatively rare, it is noteworthy that they are expressed by evolutionarily distant species. However, the systematic comparison of tool use propensities across species often requires the distinction between *stereotyped* and *flexible* tool use. Stereotyped tool use entails limited to no inter-individual variation in the form or frequency of actions directed to similar objects, whereas flexible tool use implies the use of different tools, applied to different contexts, to achieve different goals, with a dissociation of mean-end between action and purpose (Boesch 2013; Hunt et al. 2013).

Stereotyped tool use has been typically associated with invertebrates and fish, because of the relatively low cognitive abilities it requires. However, birds and mammals can also use tools stereotypically (e.g., anting in Passeriformes, a behavior that consists in whipping insects onto one’s feathers; stone-throwing behavior in Egyptian vultures to break into eggs). Yet, considering tool use in invertebrates as exclusively stereotyped would be an oversimplification. Octopuses have one of the largest and most complex nervous systems of all invertebrates, and their brain-body weight ratio exceeds that of most fishes and reptiles. They use tools in many ways, from defensive water jets for prey capture to object-sheltering as an anti-predatory strategy,

to object-handling serving the purpose of moving away unwanted items, and those examples may be characterized as flexible tool use. Stereotyped tool use is performed by all the members of a given species and sometimes by several species within a given genus, with extremely low levels of behavioral variation in the form and frequency across individuals. For instance, the hunting strategy of pit-building antlions (i.e., throwing sand at their prey once it fell inside a pit to prevent it from escaping) resembles the prey-burying of *Sphecinae* digger wasps, a closely related genus, which compress sediments on top of their nest after putting prey inside to feed their offspring. A possible explanation for this consistency is that stereotyped tool use develops from preexisting behaviors (e.g., flicking sand randomly to maintain the pits in antlions, placing objects to cache the entrance in digger wasps) and are acquired (almost) asocially, and without learning (Hunt et al. 2013). Lastly, stereotyped tool use is generally context-specific (i.e., the same object or action is not employed to attain different goals). For instance, Egyptian vultures do not place stones to hide food from competitors or do not throw them at predators to drive them away.

Instances of flexible tool use have been mostly reported in animal taxa displaying relatively high cognitive abilities, such as corvids and primates. Although flexible tool use may originate from preexisting schemata (e.g., caching behavior in New Caledonian crows closely resembles the developmentally acquired combination of objects that precedes tool use), a considerable amount of time and practice is spent to learn how to successfully use tools, via individual and observational learning, which may partly explain the high degree of inter-individual variation in the expression of flexible tool use (Hunt et al. 2013). In juvenile capuchin monkeys, the full-blown and successful form of stone-assisted nut-cracking behavior emerges after more than 2 years of unsuccessfully percussing nuts and nutshells against substrates, and upon observational learning from proficient nut-cracking individuals (de Resende et al. 2008). Termite-fishing behavior in chimpanzees share similar acquisition patterns, and individuals successfully master this complex

tool-aided foraging technique after 5 years of practice (Lonsdorf 2006).

The strong positive correlation found between relative brain size and the ability to use different objects instrumentally, in various contexts, and to reach different goals support the hypothesis that flexible tool use requires advanced cognitive skills (Reader and Laland 2002). Species that can flexibly manipulate different objects to solve functionally similar or different problems tend to outperform closely-related non-tool-using species in cognitive tasks testing for physical cognition, casual reasoning, working memory, and self-control. When comparing pit-assisted hunting behavior in antlions, sponge-assisted rostrum-covering in dolphins, twig-assisted termite-extraction in chimpanzees, stone chopper-assisted meat-processing technique in Oldowan hominins, and spear-making/using technology in prehistoric humans, there was an increase across species in the ability to hold information for later usage (i.e., working memory), expressed by an increase in problem-solution distances (Haidle 2010). When using tools, humans can understand the cause-and-effect relationships between objects (i.e., causal material reasoning); other taxonomic groups capable of performing object-assisted instrumental actions in diverse contexts may be relying on similar cognitive processes.

Intriguingly, some captive members of non-typically tool-using species are able to use objects as tools and possess cognitive skills similar to closely related species with a propensity for tool use in the wild. One way to experimentally test for the mental ability to represent the physical properties of objects (i.e., physical reasoning) is to use the two-trap tube task, a revised version of the tube-trap task. In its original version, the tube-trap task consists in a transparent tube, with food placed in the center and an underside trap into which the food will fall if moved into it. To access the reward, an individual has to maneuver an already inserted stick-tool to extract the food out of the tube while avoiding the trap. The two-trap tube task has an additional nonfunctional trap in which food can pass over a solid base, and the subject has to detect the correct side to avoid the functional trap and retrieve the food reward.

When tested on the two-trap tube task, New Caledonian crows (i.e., a typical tool-using in the wild) successfully used a stick-tool to extract the food reward; interestingly, six out of seven captive rooks (i.e., members of the corvid family that do not appear to use tools in the wild) performed similarly (Emery and Clayton 2009). Tool use may be an evolutionary by-product of other adaptive cognitive abilities, rather than an originally adaptive mental trait. What is perhaps even more surprising is that highly proficient tool users in the wild, like chimpanzees, fail popular tests for causal reasoning, like the trap tube task. Chimpanzees learn to avoid the trap after around 80–100 trials, but do not appear to transfer knowledge between different trap problems (Martin-Ordas et al. 2008). Indeed, when the trap is inverted (i.e., the trap tube task is ineffective), chimpanzees keep adopting the previously learned strategy. Similar results have been found in humans, and the effectiveness of the trap tasks for testing for causal understanding has been questioned. In the end, researchers are left with an outstanding question: Is causal reasoning necessary to use objects as tools (and if so, to what extent)? The aforementioned results should also make us cautious when considering the assumption that tool use in humans and non-human animals has a common evolutionary origin and followed similar cognitive pathways of expression.

A necessary ingredient for the expression of flexible tool use is the *propensity* to manipulate objects, which is not only a reflection of anatomical features but emerges from a combination of psychological processes determined by extrinsic and intrinsic factors (Call 2013). Indeed, capuchin monkeys and squirrel monkeys have similar hands, but they markedly differ in their manipulative propensities and their abilities to use tools. Unfortunately, there is no clear consensus on the definition of the term “manipulative propensity,” and systematic cross-species comparisons are made difficult by the use of different operational definitions. Manipulative propensity has been measured in terms of *amount* of object manipulation (i.e., frequency or duration), *complexity* of object manipulation (e.g., number

of object combinations), or *variety* in the types of object-directed actions. As such, a given species’ manipulative propensity may affect its ability to efficiently use tools across different contexts (i.e., flexibly). In the next sections, different extrinsic and intrinsic stimuli influencing the propensity and ability to use objects as tools are reviewed.

## Extrinsic Factors Affecting the Propensity to Manipulate Objects Instrumentally

### Ecological Factors

Food availability is one of the main drives in the propensity to manipulate objects, and thus it is not surprising that most instances of tool use occur within the behavioral domain of foraging activities (Shumaker et al. 2011). According to the “ecological necessity” hypothesis (Fox et al. 1999), tool use may have emerged as a need to exploit novel and hard-to-process food sources due to resource scarcity. Food scarcity may be due to ecological factors (e.g., seasonality), social factors (e.g., dominant individuals having priority of access to main food resources), and intrinsic factors (e.g., higher physiological demand during pregnancy and lactation). The diet of chimpanzees living at Bossou, Guinea, mainly consists of fruit pulp, but during periods of fruit scarcity, these animals rely on oil-palm nuts and pits, which are processed by two types of tool use: stone-aided nut-cracking and pestle-pounding behaviors (Yamakoshi 1998). The rates of tool use increase from 10% to over 30% during fruit scarcity, which indicates that tool-assisted extractive foraging is a necessary behavioural strategy for this population.

According to the “ecological opportunity” hypothesis, individuals should have the opportunity to use tools (e.g., presence of instrumentally-relevant objects or food sources that can be exploited by tool use; Fox et al. 1999). The population of orangutans living at Suaq Balimbing Research Station, in Sumatra, has significantly higher tool-assisted insect foraging rates, compared to other populations of orangutans living at different sites (Fox et al. 2004). The abundance

of insects at Suaq Balimbing Research Station is higher compared to other locations, which supports the idea that propitious circumstances may have driven tool invention in this population.

Considering the previous two hypotheses, the need and opportunity to access embedded and rich food sources during seasonal periods of food scarcity in species with omnivorous diets and extractive foraging strategies may have selected for the emergence and refinement of specific object-assisted food-procurement behavior patterns, including tool use (see also: “technological intelligence” hypothesis; Parker and Gibson 1977). In capuchin monkeys, extractive foraging strategies follow seasonal patterns, with the tool-aided exploitation of embedded invertebrates concentrated during periods of food scarcity. However, the “technological intelligence” hypothesis has been challenged mainly because tool use is rare and its phylogenetic distribution is patchy among extractive foraging and generalist primate species (i.e., only a few populations of capuchins, cercopithecines, and great apes routinely use objects as tools in the wild). Similarly, alternative ecological and functional hypotheses only partly explain the occurrence of tool use across evolutionarily related species. Thus, although those hypotheses remain generally valid, ecological factors and the evolution of complex extractive foraging skills alone cannot explain the emergence and spread of tool use behavior in the wild.

### Social Factors

The social influences an individual is exposed to may also drive the expression of the instrumental manipulation of objects as tools. Several food-provisioned groups of Japanese macaques have been reported to customarily engage in a form of culturally maintained, playful, and seemingly functionless stone manipulation often referred to as “stone handling.” However, it has been argued that the relatively relaxed dominance style of the captive Takahama group of Japanese macaques housed at the Kyoto University Primate Research Institute might have facilitated the innovation and diffusion of the only (documented) spontaneous and functional use of stone tools in this

primate species, possibly derived from the daily practice of stone handling: unaimed stone-throwing behavior mainly expressed during periods of high disturbance and serving the function of amplifying the performer’s agonistic display (Leca et al. 2008). Such differential social environments may alter not only the context of expression but also the significance of other tool use variants (Boesch 2003). In chimpanzees, the leaf-clipping behavior pattern is a tool-assisted communication signal that consists for an individual in repeatedly nipping leaf blades with its incisors and lips without eating any part of the leaf. This sound-producing display is culturally mediated and it acquired different social meanings that are population-specific: (1) in Mahale, Tanzania, it is a sociosexual display that serves the function of attracting potential mates; (2) whereas in Bossou, Guinea, it is used to initiate social play interactions; and (3) in Taï, Ivory Coast, it is an important mediator in the context of within-group male-male competition.

According to the “opportunity for social learning” hypothesis, higher levels of within-population social tolerance lead to greater manipulative propensities, because behavioral innovations, like tool use, can spread and be maintained across individuals (van Schaik et al. 2003). Social tolerance allows potential learners to be exposed to the mere presence of skilled group members (i.e., social enhancement), to the presence of tool artifacts previously employed by successful tool users (i.e., stimulus enhancement), and in some cases to demonstrators of the tool-assisted actions (e.g., emulation, imitation, and possibly teaching). The comparative analysis of behavioral data from captive rhesus, long-tailed, and Tonkean macaques showed a significant positive correlation between species-specific levels of social tolerance and the time spent manipulating novel objects, including tool use (Thierry et al. 1994). Similarly, the Goualougo Triangle chimpanzee population, in the Republic of Congo, characterized by a relatively complex tool-use repertoire, including instances of coaction (i.e., when an individual allows another to touch either the hand or part of the tool during use), exhibits levels of social tolerance and spatial

proximity that are higher than other populations of chimpanzees (Sanz and Morgan 2013). Relaxed social environments enhance opportunities for behavioral coordination among group members, visual feedback from tool-using conspecifics, and access to the physical traces left at tool-using sites by previous tool users. Such favorable circumstances are conducive to direct and indirect social learning of tool use. In an experimental study aiming to explore the social processes underlying the acquisition of novel object-directed actions in captive capuchin monkeys, seven out of nine subjects preferentially touched the area of the apparatus previously manipulated by their group members (Matthews et al. 2010). Likewise, during an object-choice task, New Caledonian crows preferentially selected the tools previously used by a conspecific demonstrator, compared to other novel objects (Kenward et al. 2006). However, extrinsic factors alone do not suffice to explain the phylogenetic distribution of tool use behavior and a given species' propensity to manipulate objects in either playful or instrumental ways. Intrinsic factors, such as motivational processes, morphological adaptations, and individual history, play a vital role in a subject's proclivity for object manipulation and tool use.

### **Intrinsic Factors Affecting the Propensity and the Ability to Manipulate Objects**

#### **Intrinsic Motivation and the Role of Object Play in Tool Use**

Broad structural similarities across various object-oriented activities (i.e., exploratory, playful, and instrumental) have been found in an extensive comparison of 74 species of nonhuman primates (Torigoe 1985). More specifically, the overall execution by adult long-tailed macaques of a probably functional activity (i.e., pounding an edible object – a hard-shelled nut – on a hard substrate) and a seemingly nonfunctional one (i.e., pounding a nonedible object – a stone – on a hard substrate) has very similar basic sequential movement components (i.e., upswing, adjustment, and strike; Pellis et al. 2019). Likewise,

the fundamental motor building blocks of stone tool-assisted nut-cracking behavior in chimpanzees include actions that are typically observed in explorative and playful object manipulation in this species. Moreover, a number of experimental studies in nonhuman primates and children found positive correlations between the frequency of noninstrumental (either exploratory or playful) object manipulation and measures of success in subsequent problem-solving tasks involving the use of these objects as tools (e.g., shorter latency to succeed for the subjects with previous object-handling experience). For example, the ability to join sticks together to make and use raking tools in order to access out-of-reach food was improved by the prior playful manipulation of sticks in captive chimpanzees (Birch 1945).

The spontaneous manipulation of objects in a nonfunctional way (i.e., play and exploration) may contribute to an individual's propensity to use these objects in functional contexts. In a free-ranging and coastal population of Burmese long-tailed macaques in Thailand that routinely use stone tools to crack open shellfish, developmental data indicate the playful manipulation of lithic material by juvenile monkeys before learning to use stones instrumentally (Tan 2017). In this species, percussive stone-tool use may be facilitated by exploratory and non-instrumental stone-directed actions gradually incorporated into foraging activity. Within the *Macaca* genus, a cluster of macaque species belonging to the *Fascicularis* taxon have a natural propensity to manipulate stones in a playful context; this intrinsic motivation may promote the integration of stones in various behavioral domains, including their functional use in extractive foraging strategies – even though this hypothesis remains to be tested. In an experimental study addressing the role of motivational processes (and previous experience) in tool use performance in great apes, extrinsic motivation (i.e., food reward as an external foraging trigger) had a negative/inhibitory effect on tool-assisted problem-solving success, whereas intrinsic motivation (i.e., the internal neophilic drive to explore a novel, even empty, apparatus) shortened the latency to solve the tool-use task (Ebel and Call 2018). This result

is consistent with studies showing that (1) high extrinsic motivation (i.e., higher interest in, and attraction to, a visible food reward during a test) decreases problem-solving performance, and (2) individuals in an atypical hunger state (e.g., due to food deprivation) performed more poorly in a food-rewarded tool task than individuals in a typical hunger state.

Play behavior, including object play, is also intrinsically rewarding, which may contribute to the maintenance of object-directed activities, particularly during the development. First, the frequency of object play is age-dependent: juveniles spend significantly more time playing with objects than adults. Second, the acquisition of flexible tool use is gradual and proceeds through several developmental stages; in long-lived animals, such as primates, it takes years for an individual to master specific and complex tool-use skills (de Resende et al. 2008; Lonsdorf 2006). During such a lengthy acquisition period, object-directed play may serve the function of maintaining high levels of intrinsic motivation (e.g., sustained interest in, and attention to, objects) in unskilled youngsters, before they can be externally rewarded as proficient tool users. Among great apes, who need several years of practice before mastering tool use (Lonsdorf 2006), chimpanzees and humans are the most frequent and versatile tool using species; interestingly, juvenile chimpanzees and children also engage in significantly more object than immature bonobos, which belong to their most closely related species, and a species that is not proficient in tool use (Koops et al. 2015). However, the propensity to manipulate objects is constrained by the physical *ability* to do it, which depends on the individual's anatomy.

### The Role of Anatomical Features in Tool Use Structure

While psychological processes affect the propensity to manipulate objects, anatomical features constrain object-directed actions. Not surprisingly, the most complex and various tool use repertoires are found in primates, and more specifically in humans, followed by great apes, whose hands possess the greatest potential for movement *complexity* and *dexterity* (i.e., grip

and grasping postures; Shumaker et al. 2011). Manipulative complexity has been structurally defined in various ways, including manipulation pattern diversity, object-substrate combination, and bimanual asymmetric coordination. In a comparative study across 36 nonhuman primate species, it was measured by the cumulative ranking of occurrence of different categories of object manipulation, based on unimanual/bimanual actions, synchronous/asynchronous use of hands and fingers, and whether the same/different objects were handled (Heldstab et al. 2016). Species displaying more complex types of object manipulation (e.g., tool use) were also able to engage in lower levels of manipulation categories (e.g., grasping and holding). However, hands are not necessary for efficient tool use; morphological characteristics of the beak (e.g., depth, shape) play a major role in the manipulative complexity of tool-using corvids (e.g., New Caledonian crows, Goffin's cockatoos, keas).

Dexterity is the ability to solve a motor task precisely, quickly, and effectively (Bernstein 1996). The same action can be performed more or less dexterously, and an individual with higher manipulative complexity may still act with little dexterity, (e.g., a naïve individual learning a new handling skill). Dexterity requires sensorimotor coordination, which needs to be greater when the action is more complex (i.e., there is a higher number of degrees of freedom to control the moving parts of the body). Dexterity in tool use necessitates a high spatiotemporal organization of the movements performed by the body-plus-tool system (e.g., hand-plus-tool in primates, beak-plus-tool – occasionally coordinated with the foot – in corvids). However, an individual's relationship with a tool does not only result from the propensity and the ability to manipulate this object; it is also affected by the functional properties of this object. Through a variety of object-directed activities, the performer *experiences* the tool.

### The Role of Experiential Learning in the Acquisition of Tool Use

Inter-individual variation in the expression of object-directed activities, including flexible tool use, exists across most taxonomic groups

(Kappeler and Kraus 2010), and in the extreme case, tool-use innovations have been documented only in one or few individuals within a species. In capuchin monkeys, individuals vary considerably in their tool use rate and success in experimental tasks, regardless of their age and sex classes (Fragaszy et al. 2004). In chimpanzees, tool-assisted foraging techniques, such as ant-dipping and termite-fishing, are acquired by individuals at different ages, and some individuals never master them (Humble et al. 2009). In the Suidae family, tool use has only been observed in few individuals of a captive population of Visayan warty pigs, and the use of sticks and barks as part of nest-building sequences was mainly expressed by lower-ranking group members including some adult females (Root-Bernstein et al. 2019). Exposure to, and *experiential learning* with, objects play an important role in the emergence of inter-individual variation in tool use.

Tool use acquisition is a continual developmental process in which an individual's understanding of the spatiotemporal relations between objects is mediated by exploratory interactions with the environment, through affordance learning (Lockman 2000). Affordances arise from the relation between a specific individual and a specific environment, with respect to achieving goals (Gibson 1979). For example, a stone affords throwing to an Egyptian vulture, pounding to a sea otter, and knapping to an Oldowan ancestral human. Likewise, object properties may be perceived differently by members of the same species. According to the "affordance learning" hypothesis, the perception of an object's physical properties determines its potential for manipulation, affording the means for goal-oriented behaviors (Lockman 2000). Watching a toddler banging an object on the ground is likely to be interpreted as playful practice for the future functional use of this object as a tool. Most flexible forms of tool use are acquired through long periods of time, during which the learner tinkers with the tool and the possibly functional consequences of its tool-mediated actions. During this critical phase of trial-and-error learning, individuals may perform irrelevant or incorrect actions, express an incomplete or misordered sequence of actions, use inappropriate tools or substrates, and apply

their actions towards the wrong goals. Tool use acquisition proceeds through a developmental process of gradual elimination of unsuccessful attempts and honing of successful behavioral strategies.

From the perspective of "affordance learning," it might not be highly relevant to distinguish between an individual attempting to use an object as a tool and an individual engaging in object play. The "affordance learning" hypothesis stems from an ecological approach to the acquisition of tool use (Gibson 1988), which is better explained by a progressive specificity in perceiving and acting on the material world than a sudden insight into the instrumental consequences of object-directed actions. Developmental data indicate that, as children acquire further haptic experience (i.e., tactile feedback about the physical properties of objects), they become more selective in their object exploration. At 6 months (i.e., when functionally directed object manipulation has not emerged yet), infants engage in discriminate exploration when interacting with different objects, by modifying their actions depending on the object properties; for instance, they wave a bell with a clapper more often and more intensely than a bell without a clapper, or they squeeze more a spongy toy than a hard one (Palmer 1989). In the Sonso chimpanzee community in Uganda, where the use of sticks as tools has not been reported, growing individuals show decreasing interest in, and manipulation of, sticks, whereas they preferentially explore other objects that are later used as tools (Lamon et al. 2018). Likewise, during the acquisition of stone tool-assisted nut-cracking behavior, capuchin monkeys gradually learn to select and match the appropriate stones with the appropriate food targets based on the physical properties of these objects (e.g., size, weight, hardness, and resistance) as well as the geographical distance between them (Spagnoletti et al. 2011).

Exposure to, and experience with, objects in a noninstrumental context not only contribute to discovering information about the properties of these objects but also help refine the executive control when handling them in a functional manner, through practice and acquisition of manipulative dexterity (Lockman 2000).

By repeatedly performing similar object-directed actions in an exploratory context, individuals acquire the sensorimotor coordination needed to become skilled tool users. As human infants develop, their object-mediated banging actions (i.e., the repetitive striking of a surface through up-down motion of the arm while grasping an object) become less structurally variable, and their movements gradually acquire the biomechanical characteristics of proficient tool-assisted percussive actions (e.g., hammering; Kahrs et al. 2012). Even though juvenile chimpanzees are capable of performing some of the behavioral building blocks of the stone tool-assisted nut-cracking activity, they will not master the complete and successful behavioral sequence until they reach adolescence. In rhesus macaques, repetitive tool-using actions gradually create novel neural projections in the brain areas that process and integrate information about the visual and somatosensory status of the training body-plus-tool system (i.e., visual, frontal, and parietal cortex; Hihara et al. 2006).

## Conclusions

Sophisticated cognitive abilities are not a necessary and sufficient requirement for the expression of all the tool use variants reported in this review. Therefore, an ideal definition of tool use should be devoid of any anthropocentric bias, such as the necessity for the performer to understand how or why a tool works. There is no doubt that tool use independently evolved in several taxonomic groups, as structurally diverse, functionally distinct, and phylogenetically rare behavioral specializations. However, the scarce and patchy distribution of tool use within the animal kingdom cannot be explained by claiming that this behavior is a proxy for intelligence. The expression of tool-mediated actions is the combined result of strategic behavioral responses to various ecological conditions (e.g., necessity, opportunity), sociodemographic variables (e.g., group composition and cohesion, interindividual tolerance), biological traits (e.g., morphological features), and psychological mechanisms (e.g., motivational

processes, sensorimotor coordination, experiential learning). Yet, the relative contribution of each of these extrinsic and intrinsic factors to the emergence of tool use in a given species remains to be determined. Arguably, one of the most promising and integrative theoretical approaches to understanding the proximate causes of tool use is the affordance learning hypothesis. More data, beyond the primate taxon, are needed to test it.

## Synonyms

Attention; Cognitive processing; Conceptual-driven; Contextual-driven; Dorsal stream; Endogenous attention; Hypothesis-driven; Illusion; Imagination; Indirect perception; Information processing; Mental image; Perception; Representation; Ventral stream

The little prince was disappointed when grown-ups misperceived his first drawing as a hat where it was originally a shadowed picture of a boa constrictor digesting an elephant (Saint-Exupery, 1943). Given the fact that his picture is deceptive for the way grown-ups' perceptual systems work, the little prince should not blame them for their fallacious perception. As the picture is ambiguous, not providing sufficient information for a grown-up to perceive, their cognitions interfere in their perception. This phenomenon is called top-down processing.

Top-down processing together with bottom-up processing underlies imagination, anticipation, prediction, memory, and learning, yet, predominantly operates in perception and regulates attention. This entry will consider top-down processing as a matter of perception and, in the last section, delve into the neural basis of top-down processing with a focus on attention. Bottom-up processing, as a counterpart of top-down processing, will be explained briefly for the sake of better understanding of top-down processing. Yet, because it is out of scope, details of bottom-up processing will not be discussed in this entry.

Top-down is one of two modes of information processing while the other one is bottom-up. Information processing has a hierarchical organization comprising two levels in general: lower-level and higher-level. Top-down and bottom-up refer to the direction of the information flow between these levels. Lower-level information is usually processed by structures at the base of the brain. Lower-level processing deals with fine details of the information, received from sensory receptors, in every aspect. For instance, in the case of an object perception (to make it easy to determine that it is an apple, for example), information processing at the lower-level tackles the following kinds of questions: *What is the shape of the object? What is the size of the object? What is the color of the object? How transparent or opaque is the object? What is the texture of the object? How soft or hard is the object? How flexible or rigid is the object? How is the smell of the object? How is the taste of the object?* Higher-level information, on the other hand, is

processed at the top of the brain by large-scale neural networks rather than specific regions. Owing to such connected neural structure, cognitive tasks and integration of different properties such as shape, size, and color are possible. Thus, as a result of higher-level processing, an individual is able to tell that a green, round-shaped, in holdable size, edible object is an apple. Reconsidering the situation of object perception, the following questions would be reasonable for higher-level: *What is the object? What is its meaning to me (actor/perceiver)? What could/should I do with it?* Let us draw an analogy here to make the higher- and lower-level distinction more clear: Imagining a puzzle, lower-level representations of the brain process to decipher every single piece of the puzzle whereas higher-level representations put all the pieces together and name the completed picture in the puzzle and interpret the meaning of it. Keeping this analogy in mind, the top-down and bottom-up processes are now straightforward.

Bottom-up processing is also known as data-driven. It takes lower-level representations as input and processes and transmits them toward the higher-level as a feed-forward mechanism. It is like expounding every single piece of the puzzle without having any clue about what that piece could belong to, and solving the puzzle by lumping them together. Not cognition but only those defined pieces of the puzzle get involved in the puzzle-solving process. The brain knows what it is only after the puzzle is completed. Briefly, the bottom-up processing does not require intervention of third parties such as memories, prior knowledge, or mental image. What is perceived purely and directly relies on sensory information.

Unlike bottom-up processing, in top-down processing, cognition interferes along with sensory information. Cognition, in higher-level, enables the brain to make an inference based on various valances when the sensory information is insufficient for perception. The inference, thereafter, flows down as a feedback mechanism to dominate and lead the information processing. The analogy drawn above between a puzzle and bottom-up processing requires modification to suit top-down processing instead: Some pieces of the puzzle could be

lost, and/or though available, some may not be precise enough to proceed. Luckily in this module, some completed puzzle pictures are available on top of the box; counting them in the puzzle-solving process helps with filling out the gaps in the puzzle. To do so, first, in the light of the lucid pieces, the actor should guess which picture on the box might be the puzzle. Then, his/her inference will lead him/her in the rest of the puzzle-solving process. Another analogy for the top-down phenomenon: An artist who sketches a dead grandmother's portrait based on the grandchild's description would know what s/he is sketching in advance; besides, s/he would assume that the grandchild may resemble the grandmother. Her/his knowledge and prediction would administer the details of the portrait. In a nutshell, in the top-down processing, what is perceived does not merely rely on sensory information; it is also influenced by beliefs, expectations, intentions, memories, and past experiences.

Conventional theory of perception is built upon a sensation-based approach which is predicated on representational realism of Locke (Lombardo 1987) and Plato (Dotov et al. 2012). According to a sensation-based approach, perception is indirect and top-down. In a sense, what an animal perceives is not the object itself, but its reflection in mind that is constructed upon sensory stimuli in the light of higher cognitive processes (Gençer 2018; Gibson 1950, 1966, 1979). Gibson denied the sensation-based approach of conventional theory. He argued that perception is, indeed, information based. In other words, perception is an active process that requires information gathering continuously via perceptual actions at that moment directly from the object and its environment (Gibson 1979). Such unlimited information is always available there for the perceiver, and it is rich enough for perception, so it does not need to be stored in memory. That means, perception is direct and, by the same token, recruits bottom-up processing (Gibson 1979). Gibson's direct perception, and so the bottom-up processing works impeccably in such cases as a toddler's learning the depth or the third dimension of objects. Yet, his approach fell short explaining perception in some situations such as illusions. Gregory suggests that studying illusion is the practical way of

understanding perception in certain aspects (Gregory 1997, 1998, 2005). The hollow mask, duck-rabbit, Necker cube, and Boring's object-ambiguous figure namely "old wife or young mistress" are only a few well-known illusions studied in perception to demonstrate the failings of bottom-up processing (Gregory 1997, 2005).

Gregory thought of bottom-up processing as if it were a photograph and drew parallels between top-down processing and a painting (Gregory 2005). Gregory, here, defines photographs as innocent and unbiased. The innocence cannot be saved anymore once the cognition gets involved in the information processing in the painter's brain; then the inclination would be found toward painters' imagination, memories, and beliefs. The hollow mask illusion (Gregory 1997, 2005) shows how cognition, and in this case visual knowledge from past experiences, dramatically affects the vision. Although stimuli through bottom-up processing reveal that the surface of the mask is concave, we still perceive it as convex because our past experiences dictate the impossibility of a concave face. Top-down processing is so strong that, even if we have explicit knowledge regarding the absurd form of the mask, our perception persists so we cannot avoid succumbing to the illusion (Gregory 1997, 2005). Note that the top-down effect is weaker when the mask is upside down; since it is an unusual position for a face, our brains consider it as if it was a regular object rather than a face. Gregory (2005) also pointed out how we live happily albeit the confusion with respect to relative movements of the sun and the earth. If we follow our gut feeling rather than science, we bet that the sun turns around the earth without any hesitation. Although studies in physics and astronomy prove that the earth turns around the sun, our perceptual feeling contradicts the reality by virtue of our implicit knowledge.

Bottom-up processing is more likely to dominate the perception of primates and human children. However, top-down processing becomes dominant in the perception of human adults owing to higher-order cognitive development. That is why the little prince should not be vexed with grown-ups. Because his drawing is not as clear as crystal, grown-ups perceive it as a hat,

which is more likely to be experienced compared to a boa constrictor digesting an elephant. Unlike the little prince's perception, adults' perceptions are restricted by their past experiences, memories, and knowledge.

In top-down processing, the object's reality needs to be inferred from sampled attributes such as color, orientation, position, and size as they are in transmission through assorted channels (Gregory 2005). Three major modalities could be considered in the account to do so: conceptual-driven, contextual-driven, and hypothesis-driven (Gregory 1980, 2005; Rauss and Pourtois 2013).

The lexical meaning of "concept" is to envisage a notion or an object with respect to all its characteristics and/or particulars. Thus, all types of specific knowledge about the object are essential in conceptually driven modality of the top-down processing. Recall how particular knowledge about a face dominated the perception in the hollow mask illusion. Perceivers' imagination, intuition, moral, memory, and/or experience regarding the object interfere with perceptual processing in this modality. Then, the crucial question comes into mind: How does the perceiver notice if it is solely a memory or imagination from the past or it is a present-time reality? Qualia is Gregory's answer to the foregoing question (Gregory 1997, 1998). There is a long debate on and various theories that are proposed based on the notion of "qualia," which is beyond the scope of this entry. Qualia is roughly defined as the subjective attributes of experiences, also known as "raw feels" that designate immediate and introspective feelings. In such a manner, qualia arouse consciousness. As Gregory (1998) suggests, close your eyes and imagine the Niagara Falls. It does not matter how strongly you fantasize, it would never be as vivid as if you were physically present at Niagara Falls in the real world at the moment. Qualia, by the fulfilled vividness, enable us to distinguish the present-time reality from past phenomenologies.

In the preceding modality, the object, on its own, was crowned leading character. In the contextual-driven modality, however, it has to share the throne with its environment/background. In real life, every single object inevitably

exists in coherence with its environment (Gibson 1979). Moreover, its significance and function are embodied in that environment. In such a sense, the surrounding of the objects provides strong hints regarding their identity. For instance, a man who is wearing a white coat and holding a sharpened instrument could be anybody while standing alone in a picture. If this man is instead placed within the background of a kitchen and is standing behind a counter with some ingredients such as vegetables and a cutting board in front of him, he is likely to be perceived as a cook. Alternatively, if the man is behind a counter again with a cutting board in front of him but now there are only stacks of meat on the cutting board and he is in a shop rather than a kitchen, he would likely be perceived as a butcher. If instead, the man is interacting with other people who look like himself, and they surround a person who is lying on an operating table in an operating room at a hospital, no more evidence is needed to determine that he is a medical doctor, more specifically, a surgeon. Furthermore, if the person who lies down on the operating table is replaced with an animal, then it is easily inferred that he is a vet. Long story short, a perceiver's knowledge and experience regarding object-environment mutuality interfere in the perceptual process, and the top-down processing appreciates the available contextual cues as it is making inference from unsensed data. A Figure such as "I3" could be anything such as a weird symbol, a letter, a number, etc. when they are shown out of context. The sentence below demonstrates how dramatically altered reading and understanding of the very same symbol can be based on the changing context.

"The Symphony No. 7 is composed by **I3EETHOVEN** and premiered with **I3EETHOVEN** himself in Vienna on 8 December 1813 at a charity concert for soldiers wounded in the Battle of Hanau."

Third, the hypothesis-driven modality is proposed by Gregory (1980, 2005) and considered in the account of action or event perception, beyond an object. Despite the tangential differences between perception and scientific hypothesis, Gregory (1980) calls attention to their overlapping similarities, inasmuch as he expressed their "*significant*

*conceptual identities*." By marking the resemblance, he advocated that hypothesizing procedure in science would guide understanding epistemology of perception. With this confidence, Gregory analyzed the perception in three phases: signals, data, and hypotheses.

Signals, as the initiating stage of perception, refer to perceptual stimuli and action potentials. Signals are measurable with standard scales or units used in physics and transmit through various physical channels (Gregory 1980). Conceptual and contextual-associated knowledge about the present object is latent in the signals. Yet, they are nothing more than random stains of ink on a piece of white paper; just as an individual, who cannot read Japanese, might see a Japanese poem on a piece of paper.

In the second phase, the neural system processes those signals to convey them into data, which embrace inferable information. In some cases, the source of the signals is precise, so the signals are well structured, and the output is clear-cut. It is unfortunately not always the case; it is rare indeed. When it is not the case, extrainformation (such as intuitions, morals, past experiences, and memories) is required for decoding the signals. Gregory (1980) noted that the mechanism converting processing signals into data is conventional rules, not physical laws. Thus, unlike signals, data do not reflect a physical scale or unit. Data is used as a source to generate possible hypotheses and select the one among them. That being the case, a predictive power is inherent in the data.

Hypothesis is the final phase. As Gregory (1980) proposed:

*...hypotheses are selections of signalled and postulated data organized to be effective in typical (and some novel) situations. Hypotheses are effective in having powers to predict future events, unsensed characteristics, and further hypotheses. They may also predict what is not true. (Gregory 1980, p. 184)*

The signals from present are enriched by past knowledge and together allow predictions about the future. This could be commented as the hypothesis, which is generated based on the present signals of reality, shaped by the knowledge and experiences of the perceiver, and so, lead his/her immediate behavior accordingly. In this view, the

hypothesis could be systematically misleading in atypical situations such as illusions.

Wlle, yuo cna aulacly raed adn uesdnatnrd tihs  
praaprgah whotuit ayn pboerlm eevn it is a taotl  
mses. Fro yuo, hveower, it is nto spurriings any  
mroe; beacsue yuo konw the resoan nwo. Yse, of  
crosue it is top-dwon pcoresnig, mroe pcreseily  
hpoytehiss-dirivng mdotliay.

The paragraph above sets a good example for hypothesis-driving modality. Although each word is written as jumbled letters, an individual still can read and understand the whole paragraph easily. Although the individual's eyes see those words as total mess, his/her brain generates possible words using all letters and picks the most likely one among those by using knowledge and past experience. So, it may not be surprising that people who read more do a better job on that.

All in all, bottom-up processing is a readily available version as an initial package for all animals as well as mankind when they are born. Top-down version is advanced subsequently with the development of higher-level cognition; thus, it is interesting that several animal species also experience visual illusions (for review see Freeberg 2019). Bottom-up processing is more primitive and important in life-or-death situations whereas top-down processing is more related to intellectual functions. Although top-down processing seems like a more advanced version, it does not overwrite the bottom-up processing. As matter of fact, the top-down version works together with bottom-up processing. With a reference to Bar (2003), Frenske and his colleagues (2006) roughly encapsulated it on a neural basis as follows. A partially analyzed data point (e.g., blurred image) is directly projected from lower-level structures to prefrontal cortex (PFC). This activity, in the following stage, triggered the temporal cortex for the predictions that are used as feedback for the bottom-up processing. Gregory (2005) also agrees that bottom-up and top-down processing should work together in harmony.

If we could see only probable objects, we would be blind to the unlikely; but this would be dangerous, as unlikely events do sometimes occur. Indeed, if we could see only expected things and events, there could hardly be perceptual learning. (Gregory 2005, p. 1245)

## Neural Basis for Top-Down Processing

In everyday life, attention is modulated by bottom-up and top-down influences. Factors such as emotional and motivational valence, knowledge, expectation, current goals, acquired significance, volition, novelty, and unexpectedness regulate attention. The success of the goal-directed behavior depends on maintaining endogenous attention and processing low-level sensory inputs by conceptual information related to the current goal by protecting it from the interference of inappropriate stimuli through top-down mechanisms. In the case of behaviorally relevant, unexpected, and salient new stimuli that may arise during goal-directed behavior, the maintenance of the attentional set should be suspended, and attention should be shifted to the new stimulus by exogenous, bottom-up mechanisms in order to analyze the nature of the new stimulus and process its sensory attributes into a conceptually coherent phenomenal experience. Top-down modulation of attention is exerted by the prefrontal cortex (PFC), parietal and limbic cortices in the schematic representation of the modulation of attentional matrix, proposed by Mesulam (2000).

Early studies, especially microstimulation studies in nonhuman primates showed that the common components of all attentional tasks are mediated by the prefrontal and parietal cortices. The dorsolateral prefrontal cortex (dlPFC) and posterior parietal cortex (PPC) activate during the working memory tasks. The motivational valence of the stimuli is largely designated by subcortical limbic and paralimbic structures that include the amygdala, orbitofrontal cortex (OFC), anterior cingulate cortex (ACC), substantia nigra, and locus coeruleus (Mohanty et al. 2008). The amygdala modulates the responses of the visual association cortex to the emotional expression of faces, hunger affects the OFC responses to the food, and cingulate cortex activates in selective and divided attention tasks. Hunger and thirst increase the response of PPC neurons to fluid and food. Frontal lobes activate in response to novel and unexpected stimuli (Mesulam 2000). The motivational valence of the stimuli is determined by the phasic dopaminergic release from the ventral tegmental area to the

nucleus accumbens, which together with OFC and ACC forms the reward circuit of the parallel frontostriatal circuits (Alexander and Crutcher 1990). In order to give the appropriate response in an attentional task, attention must be maintained, and inappropriate responses must be inhibited. This type of task such as Go-no-go activates medial PFC and connected caudate component (Booth et al. 2003).

Although these microstimulation studies in monkeys provided important information for the understanding of brain regions that contribute to the regulation of attention, the prevailing view in cognitive neuroscience is that cognitive functions are modulated not by individual regions but by large-scale neurocognitive networks. These large-scale neurocognitive networks are first described by Mesulam (1998) based on nonhuman neuroanatomical studies. Following the classical task-related studies of the nineties, the application of the fMRI BOLD signal to the resting brain by the turn-of-the-century enabled the imaging of the so-called “intrinsic connectivity networks” (ICNs) in the human brain. ICNs are a group of synchronized neural regions responsible for cognitive-emotional and sensory-motor functions in the brain (Damoiseaux et al. 2006; Laird et al. 2011; Power et al. 2011; Yeo et al. 2011).

Corbetta and Shulman (2002) defined two anatomically and functionally distinct attention systems in the human brain, i.e., the dorsal frontoparietal system and the ventral frontoparietal system. The dorsal frontoparietal system was proposed to mediate the top-down modulation of attention to locations or features, and the ventral frontoparietal system was proposed to detect unattended or unexpected stimuli, thus, mediate the bottom-up modulation of attention.

The dorsal attention network (DAN) includes the intraparietal sulcus (IPS) and the frontal eye fields (FEF) and is organized bilaterally (Vossel et al. 2014). IPS and FEF (the major hubs of DAN) contain areas with retinotopically organized maps of contralateral space, so they participate in orientation of spatial attention (Vossel et al. 2014). DAN is active when a person has directed her/his attention to an external stimulus such as reading a book or listening to a

conference, thus maintaining goal-directed attention. At this time, a sudden alarm sound activates the ventral attention network (VAN), which has the function of detecting an unexpected stimulus (stimulus-driven attention). VAN activity inhibits the active attentional set by silencing the DAN to trigger the new behavior to learn about the nature of the new stimulus. VAN's interruption of the behavior under DAN control and shifting attention to the new stimulus is called “circuit breaking” by Corbetta and Shulman (2002).

Dosenbach et al. (2007) proposed two distinct control networks for top-down processing, and both maintain task-relevant information. The fronto-parietal network (FPN), which consists of the dlPFC, inferior parietal lobule, dorsal frontal cortex, IPS, precuneus, and middle cingulate cortex (MCC), actively maintains the task-relevant information, assesses the error-related information, and monitors changing conditions of the context during the complex and goal-directed behavior. It includes the dorsal attention network proposed by Corbetta and Shulman (2002). The cingulo-opercular network (CON), which consists of the anterior PFC, anterior insula/frontal operculum, dorsal ACC/medial superior frontal cortex, and thalamus, is active through the entire task and ensures stable set-maintenance by inhibiting inappropriate response tendencies via setting an active resistance to the interference by them (Dosenbach et al. 2008).

FPN is active when the ongoing behavior is more complicated than just watching or listening and requires problem-solving, monitoring of the changing conditions of context, assessment of the new rules of new contexts, and mental flexibility. In order to accomplish such a complicated behavior by FPN, another control network CON should be active through the entire task and protect the relevant behavior from the irrelevant stimuli.

The default mode network (DMN) was originally defined that displays activation in rest-conditions and deactivation during cognitive tasks. It consists of the posterior cingulate cortex, medial prefrontal cortex, angular gyrus, and nodes in the medial temporal lobe (Greicius et al. 2003; Raichle et al. 2001). In daily life, when an awake person does not pursue a goal-directed behavior,

they are in a state of mind wandering between past, present, and future. The DMN is currently active in this person's brain. DMN is attributed to episodic memory retrieval, autobiographical memory, and internal speech, with self-related and social-cognitive processes, value-based decision-making, and emotion regulation (Menon 2015). Although it appears to be a resting-state network that deactivates during the tasks, it was thereafter shown that it does not disintegrate during task execution, but its functional connectivity and network properties change in some specific tasks such as working memory, autobiographical planning, and oddball paradigm (Vatansever et al. 2015). This suggests that DMN may also contribute to the top-down modulation of task execution by providing information about internal mentation.

## Definition

A touch screen is an electronic display monitor that identifies the touch of a finger or stylus and

allows the user to interact with the device directly rather than with a mouse or keyboard and the monitor being either based on LCD (liquid crystal display) or LED (light-emitting diode) technology. It is an input device which is pressure-sensitive.

## Introduction

The most instinctive way of communicating or identifying any object is by touching. With the technological advancement, the need of improving human-computer interaction has been increasing. Touch screen has become the dominant technology for cursor control which has brought the world into the tip of the finger. Because of its convenience, touch screen technology is used in a wide variety of applications popularly in information kiosks, POS (point-of-sale) machines, and consumer electronics, where it has replaced the functions of keyboards.

## History

Research on touch screen technology has started way back, and it's been only a few years that the technology has become an integral part of human life with advanced touch screen technology coming on in leaps and bounds in the recent time. More and more number of products are being incorporated with this technology by various organizations.

It was in the year 1965 when Eric Johnson first published his work on capacitive touch screens (Johnson 1965). In the early 1970s, the engineers from CERN, Frank Beck and Bent Stumpe, developed the first transparent touch screen (Stumpe and Sutton 2010). In the year 1972, a group from the University of Illinois developed an optical touch screen having infrared position sensors mounted on a plasma display panel (Ebeling et al. 1973). In 1973 a product was manufactured by CERN to put in use for air traffic control (CERN Bulletin Issue 2010). George Samuel Hurst in his patent first described a resistive touch screen in 1975 which was produced in 1982 (Hurst and Colwell 1974). In the same

year, a research group from the University of Toronto developed the first human-input multi-touch system. The HP 150 which was based on similar kind of technology as used in 1972 had come up with the world's earliest commercial touch screen computers in 1983 (Biferno and Stanley 1983). During the early 1980s, touch-sensitive display units were assessed for commercial aircrafts with an aim to reduce the workload of pilots so that the crew is aware of the situations of all major aspects of the vehicular operations.

The first commercial POS-based computer was developed by Gene Mosher and the first touch screen-based pocket computer in 1986 by Casio (Viewtouch.com). As consumers started using touch screen, the error due to parallax and calibration was common until 1988 (Potter et al. 1988).

In the early 1990s, the first touch screen phone was commercialized by IBM. Almost all the touch screens were resistive until in 2007 the first cell phone with capacitive screen was released by LG (Engadget.com). It was based on projected capacitive technology. Till date touch screens continue to evolve in terms of sensing capability and applications.

## Technologies in Touch Screen

In order to allow a user to interact with a screen, touch screens use different technologies. There are generally four types of touch screen technologies: resistive, capacitive, surface acoustical wave (SAW), and infrared (IR).

### Resistive

Resistive touch screen is the most common type of touch screen technology used due to its affordability and tolerance for harsh environments. This type of screen is composed of two thin transparent sheets facing each other separated by air gap. The top sheet is made up of some transparent thermoplastic polymer (polycarbonate), while the bottom sheet is made up of some glass or acrylic-type rigid material and is coated with a conductor film such as indium tin oxide. Spacers are placed in the air gap so that the two sheets don't touch

each other when the screen is not in use. When a user applies pressure by fingertip or stylus onto the outer surface, the top sheet touches the bottom sheet and becomes connected at that point. This causes a change in the resistance and an increase in the voltage. The change is then detected by the sensor connect and then sent to the controller for processing.

Resistive touch screen is further divided into 4-, 5-, and 8-wired resistive touch screens based on the way the touch coordinates are determined which actually signifies the durability and sensitivity of the entire circuit. The change in the voltage across the conductive area is based on the no. of electrodes used. The only difference between the 4-, 5-, and 8-wired resistive touch screens is an extra set of electrodes and the wires connected to these electrodes, with the 8-wired screen as the most sensitive resistive screen.

Resistive screens are generally used in hospitals, restaurants, and factories. Other than being inexpensive, these screens can also be used with gloves. But they suffer from poor screen clarity and are prone to damage by spear-like objects which makes them difficult to repair (Fig. 1).

## Capacitive

Resistive touch screens rely on the physical pressure exerted by the user's finger or stylus, whereas

**Touch Screen, Fig. 1** Resistive screen

the capacitive touch screen makes use of the conductive nature of human body. Capacitive screen is an assembly of a transparent glass material coated generally with indium tin oxide, covered with a layer to protect it from the environment. When a user touches the screen with a bare finger, conduction of electric charges occurs over the uncoated layer, and a dynamic capacitor is formed. The sensors implanted then detect the location of touch by measuring the change in capacitance at the four corners of the screen to indicate where the screen is touched. Capacitive touch screen panels must be touched with a finger unlike resistive and surface wave panels that can use fingers and stylus.

Capacitive touch screen can be categorized as surface – capacitive technology and projected capacitive technology. In surface-capacitive technology, only one side of the insulator is coated with a transparent conductor material with electrodes placed at the four corners of screen which maintains a constant voltage over the conductive layer. When a user's finger comes in contact with any part of the screen, current starts flowing from the four electrodes to the finger, and the change in the voltage and the location is identified by the sensors embedded under the screen.

In projected capacitive technology, the screen has a grid of multiple horizontal and vertical electrodes forming a matrix. When not in use, the vertical electrodes maintain a constant current, and when a finger touches the screen, the horizontal electrodes are triggered initiating the current flow between the finger and that area of the screen which creates an electric field. The sensors instantly sense the location.

Capacitive touch screens are commonly used in mobile phones. Although the screens are expensive, they are more sensitive and have high clarity (Fig. 2).

## Surface Acoustic Wave

Surface wave acoustic (SAW) touch technology is much more advanced than the earlier discussed technologies. It detects the point of touch on the screen by tracing ultrasonic waves that are generated at the edges of the screen and reflects back

**Touch Screen, Fig. 2** Capacitive screen

and forth across its surface. A part of the wave is absorbed when the panel comes into contact with the finger interrupting the waves, and by using a transducer, the absorption of the ultrasonic waves is recorded which is then processed. Instead of using light and materials which do not absorb pulse, this technology uses sound which delivers excellent quality.

SAW screens are durable and scratch proof, and if scratched, sensing function remains unaffected. High clarity and resolution make this technology find its use in devices used for monitoring and also in ATMs, information kiosks, and medical equipment but can cease to respond when oil, dirt, or any solid stain rests on the screen (Fig. 3).

**Touch Screen, Fig. 3** Surface wave acoustic screen

**Touch Screen, Fig. 4** Infrared screen

This screen technology finds application in kiosks, outdoor installations, POS systems, and factory automation. It offers great clarity but is sensitive to dirt and moisture so inapplicable in industrial areas (Fig. 4 and Table 1).

## Infrared

Infrared touch screen is a popular technology based on infrared beams transmitted by light-emitting diodes (LEDs) and photodetector pairs around the edges of the screen, instead of using any thin film or glass layer. When a finger comes nearer to the display screen, the infrared rays are blocked, and the interruption in the pattern of LED beams is detected by the photodetectors. These LED beams cross each other in vertical and horizontal coordinates which helps the sensors to trace the exact location of the touch.

## Components of a Touch Screen System

The touch screen system has two parts: hardware and software. The hardware architecture consists of microcontroller, numerous interfaces, and driver circuits. The system software is developed using a collaborative programming language.

The three major components of a simple touch screen are a touch sensor, a controller circuit, and a software driver. The touch screen is combined with a display unit and a computer to make a touch screen system.

*Touch sensor:* The sensor has an electrical current or signal flowing through it. When a user

**Touch Screen, Table 1** Presents a brief comparison between all the technologies

| Properties        | Screen type      |                    |                  |                    |
|-------------------|------------------|--------------------|------------------|--------------------|
|                   | Resistive        | Capacitive         | Saw              | Infrared           |

| Sensitiveness     | Low              | More               | More             | Up to some extent  |
| Humid resistant   | Resistant        | Not resistant      | Not resistant    | Resistant          |
| Scratch resistant | Not              | Up to some extent  | Resistant        | Resistant          |
| Muti-touch        | Does not support | Supports           | Does not support | Supports           |
| Screen size       | <25 inches       | > 12 inches        | <32 inches       | >32 inches         |

touches the screen, it causes a change in the signal. This change in the signal is used to determine the location of the touch on the screen.

*Controller:* A controller should be connected between touch sensor and computer. It collects the information from the sensor and translates it for understanding of PC.

*Software driver:* The driver allows the computer and touch screen panel to work together. It commands the operating system to interact with the information that is sent by the controller.

**Application – Touch Screen Technology for the Visually Impaired**

Recently, touch screen technology has been trying to help the visually impaired person to access information. In order to test a blind user’s capacity in distinguishing and identifying basic geometric objects presented on a touch screen, various models such as vibration-only modal, audio-kinesthetic, or multimodal vibro-audio solutions are being under study.

In vibration-only modal, the finger path trails produced by testers and their haptic exploration strategies are analyzed when they attempt to recognize basic shapes and objects presented on a touch screen measuring the accuracy, user’s average response time, duration of each finger stroke, etc. (Southern et al. 2012; Tekli et al. 2018). To access basic shapes and charts on vibrating touch screens, vibro-audio interface has been provided between 2010 and 2015. These interfaces

combine touch screen vibration and audio feedback, which allows the blind users to explore graphical information such as bar graphs and indoor navigation layouts by combining the finger movements over the screen synchronized with audio and vibration signals when the user touches the elements on the display unit. In multimodal vibro-audio solutions, while using the screen, a haptic feedback through external vibrators fixed to the fingers of user is added. Multiple modalities such as audio, vibration, and haptic cues were combined together to provide the solutions. This could prove very useful in allowing a visually impaired person to access geographic maps, to navigate inside and outside buildings, and to access graphs and mathematical charts.

However, there are certain issues such as long response time taken by blind users to recognize a basic shape, less correlation between the shape’s surface and user’s vibration trails, etc. These issues need to be further investigated to make touch screen technology optimal enough for better accessibility for the visually impaired persons.

**Application – Touch Screen Technology for the Motor Impaired**

People with motor impairments are either able to use only the back of their hand or elbow to touch or unintentionally touch with multiple parts of their hand. The requirement of a proper touch by landing fingers on the intended area on a

touch-sensitive screen is beyond the ability of a motor impaired person.

A technique called smart touch was introduced allowing the motor-impaired users to touch the target point in their most comfortable way (Anthony et al. 2013; Mott et al. 2016). An algorithm is designed that maps the total number of touch areas to the user's intended location. It calculates the coordinates of users' intended locations closer to actual intended targets by detecting the most relevant touch of the user.

However, this is a vital step in the direction of improving touch precision for people with motor impairments which was tough previously. But it is still challenging in finding out the effectiveness of such kind of smart touch technology on smartphones and computers.

## Trace Strength

Evan T. Curtis  
Booth University College, Winnipeg, MB,  
Canada

## Definition

Trace strength refers to the accessibility of a particular memory at a given time.

## Introduction

Many models of memory assume that memories are stored as unique traces. The accessibility, or ability to be retrieved, of a trace is typically referred to as its strength. Trace strength can be influenced by a variety of factors (e.g., repetition of information). Trace strength is used as evidence for a variety of decisions and judgment (e.g., recognition of a previously studied item).

## Classic Conceptualization

Trace strength is an important component of many early models of memory. Wickelgren and Norman's (1966) trace-strength model was the first model to explicitly incorporate the concept. According to their model, a piece of information (e.g., a word to be remembered in a short-term memory task) is represented as a unique trace in memory. At baseline, the activation of that trace is zero. Upon presentation of the word, the activation of the trace increases. The activation then begins to decay exponentially until it reaches zero. The strength of a trace at a given time can be used as evidence for a variety of judgments inside and outside of laboratory tasks. There have been many extensions to the classic model (e.g., Wickelgren 1975; Wickelgren and Berian 1971), but each model contains the same core premises and assumptions.

## Factors That Influence Trace Strength

### Delay Between Encoding and Retrieval

Increasing the amount of time between encoding and retrieval decreases trace strength. This decrease is a natural consequence of the fact that trace activation decays over time. It is worth noting that most trace-strength models are agnostic about whether trace decay is passive or a result of interference. Regardless, as the activation of a trace reduces over time, its strength decreases.

### Repetition/Frequency of Exposure

Repeated exposure to an item increases trace strength. When an item is encountered the first time, the activation of its trace increases and begins to decay. If the item is encountered again before its trace activation has decayed to zero, it boosts to a greater activation than on the first encounter. A natural consequence of this pattern is that more common words (i.e., high-frequency words) will, on average, have a greater trace strength than uncommon (i.e., low-frequency words).

## Elaborative Processing

In standard conceptualizations of trace-strength models, elaborative processing increases the strength of a trace. For example, if items are studied by counting the number of vowels (shallow processing), they will have lower trace strength than items studied by generating an antonym (deep/elaborative processing; Craik and Lockhart 1972). This pattern requires an additional assumption that elaborative processing results in a greater increase in trace activation.

It is well known that elaborative processing does not necessarily result in better memory performance. Instead, the match between processing at study and test is critical, a phenomenon typically referred to as *transfer-appropriate processing* (Morris et al. 1977). This pattern is inconsistent with a purely strength-based account of memory and is typically leveraged as evidence against pure trace-strength models.

## Standard Applications of Trace Strength

According to trace-strength models, trace strength is used as evidence to guide a variety of judgments that can be tested in the laboratory.

### Recency Judgments

Trace strength is a strong indicator of how recently an item has been encountered. On average, recently encountered items will have greater trace strength because the traces' activations have had less time to decay.

### Frequency Judgments

Trace strength is also a strong indicator of how many times an item has been encountered within a certain time period. On average, more frequently encountered items will have greater trace strength because the traces' activations will have been boosted multiple times.

### Recognition Judgments

Trace strength can be used to discriminate studied from unstudied items in a standard recognition memory task. In a recognition task, participants study a set of items (typically words). They are

then shown the same words they studied intermixed randomly with new, unstudied words. They are asked to determine whether each word was studied or not. In standard models, trace strength is compared against some decision criterion that, if exceeded, results in a “studied” judgment.

## Conclusion

Trace strength is an important concept in memory theory, acting as an index of the accessibility of a memory in many models. Trace strength can be influenced by a number of factors, including decay, repetition, and depth of processing. Trace strength can be used as evidence in favor of many judgments, including recency, frequency, and recognition. Although classic models in which trace strength is the sole basis of memory performance are insufficient, trace strength is a concept that is incorporated – sometimes tacitly – into most conceptualizations of memory.

## Transcranial Magnetic Stimulation (TMS)

Natalie A. Matheson and John N. J. Reynolds  
Department of Anatomy and the Brain Health  
Research Centre, University of Otago, Dunedin,  
New Zealand

## Introduction

Transcranial magnetic stimulation (TMS) was pioneered in the mid-1980s by Anthony T Barker and colleagues, as a method to noninvasively activate brain circuits (Barker et al. 1985). The impact of TMS on neuroscience and

neurology is apparent in its widespread current use as an experimental tool to investigate neural circuitry. It is also under extensive investigation for its potential application in clinical settings where it may be used to treat neurological and mood disorders, such as stroke, Parkinson's disease, and depression.

## Principles of Operation

Transcranial magnetic stimulation operates on the principle of electromagnetic induction, first described by Michael Faraday in 1914. A magnetic field changing in time, applied to a conductive material, induces an electric field in that material. In the case of TMS, a large electric current is passed through the stimulating coil, causing it to act as an electromagnet and generate a magnetic field. The flux lines of this magnetic field are generated perpendicular to the plane of the coil and pass painlessly through the scalp and skull and into the conductive tissue of the brain. The induced electric field flows perpendicular to the magnetic flux lines and thus travels in parallel with the surface of the brain and in the opposite direction to current flow within the stimulating coil (Hallett 2007). Depending on the orientation of the coil, the electric field activates neural elements such as axons from neurons, which are oriented in parallel with it, or cell bodies and their inputs from other neural elements.

## Human Application

The first human experiments using magnetic stimulation delivered magnetic pulses to the median nerve in the forearm and generated a "twitch" in the ipsilateral thumb which could be recorded by electromyograph (EMG). In 1985, Barker et al. first described application of magnetic stimulation to the brain. Transcranial stimulation was found to be painless and was easier to apply than the more invasive electrical stimulation techniques in common use at the time. Single magnetic pulses applied to the scalp overlying specific areas of the motor cortex were shown to generate twitches

in muscles controlled by the stimulated areas of the cortex. These muscle twitches are called motor evoked potentials (MEPs) and are observed primarily in the limbs opposite to the site of brain stimulation (Fig. 1).

Measures of the delay between stimulation and response and the amplitude of the response recorded from the muscle provide information on conduction velocity and strength, respectively, of neural transmission between brain and muscle (Kobayashi and Pascual-Leone 2003). Initially, single pulse TMS was employed to monitor the integrity of pathways between brain and spinal cord during neurosurgery and to assess motor function in individuals living with neurological conditions.

**Transcranial Magnetic Stimulation (TMS), Fig. 1 Representation of motor evoked potential recording in a human.** (a) The TMS coil (purple rings) is placed over the motor cortex and single pulses are applied. These pulses activate contralateral muscles which are represented by the area of the cortex that is being stimulated. Motor evoked potentials are recorded from the activated muscles using electrodes placed over the skin or into the belly of the target muscle. (b) Representation of a motor evoked potential recorded from the contralateral hand. Purple arrow indicates delivery of the TMS pulse, and the recording shows the amplitude in millivolts (mV) recorded over time in milliseconds (ms)

Predicting the effect of single pulses of TMS on brain circuits is complex, due to an interaction between various parameters of the stimulation itself, and physiological features of the human brain. For instance, the orientation of magnetic coil placement and therefore orientation of the induced electric field affects the amplitude of MEPs generated by TMS (Mills et al. 1992). Magnetic stimulation seems to be most effective at activating neurons which project horizontally within the cortex as opposed to those which project at right angles to the cortical surface (Day et al. 1989). The intensity at which TMS is delivered also determines which type of cortical neuron will fire in response to each stimulus, due to differences in membrane properties of the neurons or their depth from the cortical surface. Neurons with a low action potential “threshold” may be preferentially activated at low TMS intensities while higher threshold neurons remain silent (Moliadze et al. 2005). Neurons located in more superficial layers of the cortex are also more readily activated due to the limited ability of the magnetic field to penetrate through brain tissue. Thus, many factors contribute to determining the response of the brain to single pulses of TMS, not all of which are well understood.

### Inducing Long-Term Changes in the Brain with TMS

An area that has been explored intensely with TMS is the ability to induce long-term changes in neural activity. The approach is to stimulate specific regions of the brain with an extended train of pulses (repetitive TMS, rTMS) in order to effect physiological changes that outlast the period of stimulation. In the first investigation of rTMS using low frequencies, Wassermann et al. (1996) showed that 3 min of continuous stimulation at 1 Hz reduced MEP amplitude for up to 2 min poststimulation. Through this work, it became apparent that rTMS had the capacity to alter activity of the cortex over a prolonged period and may therefore be effective in the treatment of some neurological disorders.

Since then, the effects of rTMS on motor cortex activity and function in humans have been extensively investigated. Most studies agree that low frequency rTMS (<1 Hz) produces inhibition of activity within motor pathways while high frequency rTMS (>5 Hz) facilitates activity. These findings are consistent with those observed in fields investigating the phenomena of long-term potentiation (LTP) and long-term depression (LTD) in the role of learning and memory within the hippocampus. This has led to the hypothesis that rTMS was inducing LTP and LTD in stimulated regions of the cortex. Repetitive TMS-induced changes in cortical activity, however, are less robust than those observed in the hippocampus and display a large amount of inter-subject variability in both humans and animals. Despite this variability and inconsistency between studies, the use of rTMS has progressed from probing the physiology of various pathways and systems in the brain to application to a wide range of neurological conditions.

The use of repeated TMS pulses adds additional layers of complexity in determining its effects on the brain. Adding multiple pulses together to form a stimulus train introduces additional parameters, such as stimulus-train length, frequency, number of pulses delivered, and their temporal pattern. All of these parameters may differentially affect the responses of the intended target neurons to rTMS. For instance, the application of pulses in short groups of bursts, repeating at a frequency reminiscent of theta waves in the brain, has shown some utility in strengthening or weakening neural circuits, depending on the timing between the burst (Huang et al. 2005). However even this approach, which has found most utility, shows wide variability in response pattern between individual humans and animals in experimental investigations. Due to the vast parameter space and individual variation, the most effective way to deliver rTMS to cause lasting changes in neural activity is not yet well characterized. For this reason, meta-analyses of studies that have applied rTMS in order to treat neurological disorders such as Parkinson's

disease and stroke have yet to recommend its routine use in a clinical setting. Thus far, only in intractable depression in humans has rTMS advanced into regular human use.

## Gaining Insight from Animal Models

One of the difficulties in gaining a clearer understanding of TMS is that our impressions about its effects on the brain usually come from an indirect measurement of the response in muscles. When activity is recorded directly from the brain following stimulation, responses are not as stereotypical as observed with MEP recordings, but arguably provide greater insight into the cellular effects of TMS that might be harnessed to treat neurological diseases. Due to the invasive nature of the techniques, recording from neural circuits is generally only possible in animals. However, this on its own presents a set of challenges. Brains of traditional laboratory animals such as rats and cats are much smaller than those of humans, and traditional human TMS coils are large. Thus, a much larger area of the brain is activated than would be in humans, leading to less spatially specific effects. To overcome this, smaller, animal-specific coils have been designed, and while activation is more focused, they are still excessively bulky and restrict the placement of other experimental apparatus required for recording from the brain. In addition, there are significant technical challenges in decoupling the direct effects of TMS from the neural recording apparatus, so that the recording can faithfully report the responses of neural circuits to TMS.

Experiments that have been performed in animals to investigate the neural effects of TMS have used techniques such as extracellular recordings from single neurons, and field potential or optical recordings using voltage sensitive dyes, to measure the activity of large ensembles of neurons. These experiments have shown that neuronal activity following application of TMS pulses can depend on the nature of other stimuli the brain is attending to at the time of stimulation. For

example, the activity of single neurons in the visual cortex of cats in response to TMS differs depending on whether or not a visual stimulus is presented to the animal during TMS (Moliadze et al. 2003). As well as cats, responses to single pulses of TMS in whole brains have been recorded in anesthetized rats and awake monkeys. In the majority of cases, responses to TMS pulses vary from neuron to neuron, however similar overall patterns of activation are seen (Mueller et al. 2014). Immediately following each TMS pulse, an increase in action potential firing rates is observed, generally followed by a period of suppression of activity. Across studies, however, the timing of these periods of facilitation and suppression vary considerably, making it difficult to define a precise mechanism of action for a given TMS intensity.

The use of animal models in TMS research is ongoing. Significant innovation is required to overcome the challenges of size and to enable recording from single and multiple neurons under conditions relevant to that experienced in the human brain. Work combining TMS with neural recordings in animal models is essential, in order to further our knowledge of the cellular effects of TMS on the brain.

## Conclusion

While TMS has proven to be a useful tool for scientists probing the physiology of various neural circuits, a lack of understanding of the basic mechanisms of action is hindering its progress in treating neurological disease clinically. The use of animal models allows scientists a promising opportunity to probe the effects of TMS on the brain at both a single neuron and system level but requires significant technological advance to improve the ability to stimulate and record neurons simultaneously. It is hoped that with a better understanding of the cellular mechanisms harnessed by repetitive TMS, stimulation protocols may be optimized to drive specific neural changes that may facilitate recovery from a range of neurological disorders.

## Definition

Transcription is a process in which information from a gene is converted in the form of RNA.

## Introduction

Transcription is the copying of a gene's DNA sequence to make an RNA molecule. It is a process in which ribonucleic acid (RNA) is synthesized from DNA. The word “gene” refers to the functional unit of the DNA that can be transcribed. One of the two strands of DNA acts as a template (noncoding strand or sense strand) and results in the production of working copies of RNA molecules. The other DNA strand, which never participates in transcription, is called a coding strand or antisense strand. Transcription is performed by enzymes called **RNA polymerases**, which link nucleotides to form an RNA strand (using a DNA strand as a template).

## Stages of Transcription

Transcription consists of three stages: initiation, elongation, and termination.

### Initiation

The process of transcription begins when the RNA polymerase recognizes and binds together with one or more general transcription factor(s), in the case of eukaryotes and  $\sigma$  (sigma) factor, in the case of prokaryotes, to a specific DNA sequence, which is called a “promoter.” A number of transcription factors interact with eukaryotic promoter regions. In humans, about six transcription factors (TFs) have been identified (TFIID, TFIIA, TFIIB, TFIIF, TFIIIE, TFIIH). It has been postulated that the TFs bind to each other, and in turn to the enzyme RNA polymerase. This forms an RNA polymerase-promoter “closed complex” (Watson et al. 2013).

### Elongation

One of the strands of the DNA, the *template strand* (or noncoding strand), is used as a template for RNA synthesis. After transcription is initiated, the DNA double helix unwinds and RNA polymerase reads the template strand. It adds nucleotides to the 3' end of the growing chain. New nucleotides are added at an approximate rate of 42–54 nucleotides per second in prokaryotes (Dennis and Bremer 1974), whereas in eukaryotes the speed is approximately 22–25 nucleotides per second (Izban and Luse 1992). RNA polymerase forms the RNA strand using base pairing complementarity rule (in RNA, Uracil is present instead of Thymine). RNA polymerase travels through template strands from 3'  $\rightarrow$  5' and the coding (nontemplate) strand is used as a reference point. Notably, transcription always occurs in 5'  $\rightarrow$  3'. In addition to that, elongation also involves a proof-reading mechanism to get rid of bases that have been wrongly incorporated. Proof reading is carried out by RNA polymerase. There are two ways in which the mRNA repair is carried out.

1. Pyrophosphorolytic editing
2. Hydrolytic editing

If any incorrect nucleotide is added to the template DNA, the RNA polymerase will stop and then it will either proofread the transcript or continue without correcting (Watson et al. 2013).

### Termination

Terminator sequences have been observed very close to the ends of noncoding sequences (Clancy 2008). The process of transcription is terminated by termination signals. Two types of termination have been identified.

1. Rho ( $\rho$ )-Dependent Termination

A specific protein, named  $\rho$  factor, binds to the growing RNA. In the bound state, it starts acting as ATPase, terminates transcription, and releases RNA. The  $\rho$  factor also causes the dissociation of RNA polymerase from DNA.

2. Rho ( $\rho$ )-Independent Termination

The formation of hairpins of newly synthesized RNA results in termination of transcription in this case. This is due to the presence of palindromic sequences. As an analogy, a palindrome is a word that reads the same in both forward and backward directions, e.g., Malayalam, Rotor, etc. The presence of palindromes in the base sequence of DNA template (same when read in opposite directions) in the termination region is well established. Because of this, the newly synthesized RNA folds to form hairpins (due to a complementary base pairing) that cause termination of transcription (Lykke-Andersen and Jensen 2007).

## mRNA Processing in Eukaryotes

In eukaryotes, primary transcripts of mRNA molecules are processed after transcription: they are **spliced** and have a **5' cap** and **poly-A tail** put on their ends. This step consists of three stages:

- (i) Capping – In the capping process the triphosphate group is replaced with another structure, which is referred to as a “cap,” which is added by the enzyme guanylyl transferase.
- (ii) Polyadenylation – This is the addition of the adenines (A) at the 3' end, which is catalyzed by the enzyme poly (A) polymerase.
- (iii) Splicing – It involves removing the introns and adding the exons.

Transcription is controlled separately for each gene. In short, **transcription** is the process of copying out the DNA sequence of a gene in the similar alphabet of RNA.

## Conclusion

The goal of transcription is to make an RNA copy of a gene's DNA sequence. For a protein-coding gene, the RNA copy, or **transcript**, carries the information needed to create a polypeptide or protein. Eukaryotic transcripts need some processing before getting translated into proteins.

Christopher Balakrishnan<sup>2</sup>

<sup>1</sup>Department of Psychology, City University of New York, New York, NY, USA

<sup>2</sup>East Carolina University, Greenville, NC, USA

## Definition

The set of all RNA molecules produced in a particular condition within a given cell, tissue, or organism of interest

## Introduction

Transcriptomic studies investigate the RNA content (or gene expression), including messenger RNA (mRNA) and noncoding RNA, within a given cell, tissue, or organism. Typically, from a given transcriptome, the relative transcript expression is compared between two or more conditions. In doing so, researchers are improving our understanding of the underlying mechanisms controlling behavior and cognition.

## Technological Advances Promote Transcriptomic Research

Prior to the availability of transcriptomic approaches, researchers were restricted to analyses of individual genes of interest, unable to document the simultaneous expression patterns for thousands of transcripts in response to behavioral experiences. High-throughput methods developed in the mid-1990s and 2000s yielded two techniques to survey the transcriptome more broadly: microarrays and “next-generation” RNA sequencing (RNA-seq) (Lowe et al. 2017). For each method, RNA is isolated from the sample and converted to a more stable complementary DNA (cDNA). Microarrays measure the relative abundances of cDNA for thousands of transcripts bound to the microarray slide. Microarray studies,

however, are restricted to analyses of expression patterns for only the subset of transcriptome available on the given array slide, and slides have primarily been developed for model or economically important species. RNA-seq, by contrast, provides a relatively unbiased catalog of the transcriptome by broadly identifying the nucleic acid sequences of the cDNA sample and quantifying relative transcript abundances between samples and treatments. Although RNA-seq was initially very expensive (>\$1000 per sample), new technology and protocols (e.g., TAG-seq; Meyer et al. 2011) continue to reduce the cost of this approach. RNA-seq data analysis requires significant computational resources, but the research community has now developed a rich suite of open-source and proprietary software to facilitate analyses (Conesa et al. 2016).

## Transcriptomics in the Brain

Understanding gene expression in the brain has been a long-standing interest in behavior and cognition research. With the advent of transcriptomic profiling, studies are now able to pinpoint numerous genes with expression levels related to the behavior of interest, most of which were previously overlooked in candidate gene studies. Correlations among genes in response to behavioral experiences or phenotypes can further determine important molecular pathways and yield new hypotheses regarding the underlying functional mechanisms controlling behavior (Robinson et al. 2008). RNA-seq in particular provides researchers the ability to embrace phenotypic variability of non-model organisms (Calisi and MacManes 2015), to understand not only the genes associated with behaviors but also how behaviors evolve (Bell and Robinson 2011).

Transcriptomic studies alone, however, do not resolve causal mechanisms underlying behaviors of interest. Experimental support via genetic manipulations, such as gene silencing or editing, can help to distinguish causation from correlated gene expression patterns (Bendesky et al. 2017). Yet, behavioral and cognitive functions are

regulated by multiple genes that interact in networks, further complicating efforts to determine exactly how gene expression relates to behavior (Harris and Hofmann 2014). Recent efforts that link expression profiles with variants in the DNA can help to identify genetic variants that alter gene expression, known as expression quantitative trait loci (eQTLs; Majewski and Pastinen 2011). Coordinating transcriptomics with other genomic tools, in both model and non-model systems, holds great promise to provide insights into the molecular mechanisms underlying behavioral functions that were only recently made available.

## Conclusion

Identifying the genetic factors that control behavioral and cognitive responses is a major challenge. Candidate gene studies provided foundational studies of the genetics involved in brain-behavior relationships. Now transcriptomics is rapidly building on this knowledge base and contributing to a more integrative understanding of behavior and cognition.

## Transection

Priyanka Verma<sup>1</sup> and Umesh Kumar<sup>2</sup>

<sup>1</sup>Department of Molecular and Human Genetics, Banaras Hindu University, Varanasi, India

<sup>2</sup>Centre for Cellular and Molecular Biology, Hyderabad, India

## Synonyms

To divide by cutting transversely/longisection

## Definition

Transection is usually straight line along which measurements or observations are made at regular intervals.

## Transection

Transection is a dissection of body transversely via accident or experimental purposes. Accidental transection primarily includes spinal, liver, and nerve transection, all of which may cause injury. Experimental transections are those which prepare animals or human cadavers for anatomical exploration. Transection also allows ethologists and anatomists to study various animal species.

Priyanka Verma and Umesh Kumar contributed equally with all other contributors.

Before transecting any structure, the important step is to separate the part of body from underlying tissues by blunt dissection, then insert a trimmed instrument underneath it, and cut it upward. Scissors and blunt blades are used for this purpose. Some important transection such as spinal, liver, brain, and nerve and its resection procedure are discussed in the next section.

## Brain Transection

Brain transection helps to understand the intricate and internal structure of the brain. Anatomists discovered that the hypothalamus is responsible for biting, clawing, and hissing in canines with the use of transection technique (Dewey and Da Costa 2015). Multiple coronal sections of the human brain are used to study the structure of the brain and find out novel neurologic anatomical markers for diagnostic purposes (Mai et al. 2015). Henry Molaison suffered from epilepsy. After case study, a surgeon transected his hippocampus region for the treatment of epilepsy. After transection of hippocampal region, the patient's epileptic attack is normal, but he suffered a severe memory loss. Researchers concluded from this transection that hippocampal region is active during memory formation and later recall (Kalat 2015).

## Spinal Cord Transection

The internal anatomy of spinal cord is clearly visible in a transverse section. A transverse section shows white matter in the periphery, gray matter inside, and a tiny central canal filled with cerebrospinal fluid at its center (Chandler et al. 1993). The canal is surrounded by single layer of special kind of glial cells, i.e., the ependymal layer. The ependymal layer is the gray matter, which shaped like the letter "H" or a butterfly. The H shape and size of the gray matter vary according to spinal cord level. At the lower levels, i.e., away from the brain, the ratio between gray matter and white matter is greater than in higher levels, i.e., closer to the brain, mainly because lower levels contain less ascending and descending nerve fibers (Brown 2012).

Spinal cord transection also results in a loss of function such as mobility or feeling. Transections can be complete, incomplete, or hemitranssections.

Complete transection is complete loss of motor and sensory functions of the body below the transection level. It is the most devastating nerve injury. Incomplete transection is partial loss of motor and/or sensory functions of the body, whereas hemitransection is caused by damage to one half of the spinal cord and motor functions with loss of temperature and pain sensation. Spinal cord transection can be diagnosed by clinical and radiological evaluation. Immediate immobilization and alignment of spine at the accident site followed by surgery are the available treatment for spinal transection (Scholtes et al. 2012).

### Liver Transection

Liver anatomy comprises into eight functionally independent segments based on transversal plane. Each segment of liver has its own vascular inflow, outflow, and biliary drainage. There is a branch of the portal vein, hepatic artery, and bile duct in the center of each segment, and in the periphery of each segment, there is vascular outflow through the hepatic veins. This classification of liver is known as Couinaud classification (Vauthey et al. 2012). Ultrasonography, computed tomography, magnetic resonance, and radiography are the technique used for assessing the anatomy and damage to the liver. Damage/transversal cut to the liver due to accidental transection results in excessive hemorrhage (Heriot and Karanjia 2002; Ronnie 2007).

### Nerve Transection

Nerve transection is transversal nerve injury that results in damage in the endoneurium layer, i.e., myelin sheath of nerves, axon, and demyelination in the neuron. It is classified into three types based on the occurrence of demyelination and the degree of axons injury and the injury of the connective tissues of the nerve. First level is neurapraxia, which is defined by focal segmental demyelination without damage to the axons or the connective tissues. It is mildest form of injury that can be easily recovered. Another is axonotmesis, which deals with either axon damaged with intact myelin sheath, both axon and myelin sheath damaged. Neurotmesis (nerve and the nerve sheath are disrupted) is the most severe form of peripheral

nerve injury, which is a complete transection of the axons and connective tissue layers of the nerve (Geuna et al. 2009).

 Department of Biotechnology, IMS Engineering College, Ghaziabad, UP, India  
 Department of Biotechnology, School of Engineering and Technology, Sharda University, Greater Noida, India

## Synonyms

[Genetically modified](#)

## Definition

Transgenic refers to an organism that contains genes from another organism introduced into its genome through genetic engineering techniques.

## Introduction

A transgenic, or genetically modified, organism is one that has been modified through recombinant DNA technology, which involves either combining DNA from different genomes or inserting foreign DNA into a genome (Pray 2008). That is, a transgenic organism is one that contains a gene or genes (from other organisms) that have been artificially inserted.

## Transgenic Organisms

A transgenic animal, for instance, would be an animal that underwent genetic engineering. It contains material from at least one unrelated organism, e.g., from a virus, a plant, or from another animal. This process of introducing an exogenous or foreign gene is transgenesis.

GloFish are a type of transgenic zebrafish (*Danio rerio*) that have been modified through the insertion of a green fluorescent protein (*gfp*) gene. There are several *gfp* gene constructs, each encoding a different colored phenotype, from fluorescent yellow to fluorescent red. US Food and Drug Administration has approved GloFish for human use. It is the only recombinant-DNA animal that has been approved for human use. Approval of their use has raised important questions about whether, and to what extent, genetically modified animals should be made available to consumers (Pray 2008).

A **transgene** is a gene or genetic material that has been transferred by any artificial techniques from one organism to another. The introduction of a transgene (called “transgenesis”) has the potential to change the phenotype of an organism (Clark et al. 1993).

## Applications

One of the essential applications of transgenesis is for experimental research processes. Animal models are being created to introduce a particular disease for experimental studies. These models are referred to as transgenic disease models. An

experimental mouse model, specifically referred to as a transgenic mouse, is a mouse with a piece of foreign DNA integrated into its genome through recombinant DNA techniques. Most transgenic organisms are generated in the laboratory for research purposes. For example, “knock-out” mice are transgenic mice that have a particular gene of interest disabled. By studying the effects of the missing gene, the normal function of the gene can be understood in a better way.

## Examples

Transgenic organisms have also been developed for commercial purposes. The most famous examples are food crops like soy and corn that have been genetically modified for pest and herbicide resistance. These crops are widely known as GMOs (genetically modified organisms). There are some other prominent examples of transgenic organisms with commercial value.

1. **Golden Rice:** It is a genetically modified rice that produces beta-carotene, the precursor to vitamin A. Vitamin A deficiency is a public health problem for millions of people around the world, particularly in Africa and Southeast Asia. In 1997, five million children developed xerophthalmia, a medical condition caused by vitamin A deficiency, in Southeast Asia alone (Sommer 1989). Of those children, nearly a quarter million went blind (Burkhardt 1997). To combat this, scientists used biolistics to insert the daffodil phytoene synthase gene into Asian indigenous rice cultivars (Burkhardt 1997). However, Golden rice is still awaiting regulatory approval.
2. **Transgenic Goats:** These goats have been modified to produce FDA-approved human antithrombin (**ATryn**). It is used to treat a rare blood clotting disorder in humans. Transgenic goats have also been made to produce spider silk, which is one of the strongest materials, in their milk.
3. **Genetically Modified Bananas:** These genetically engineered bananas contain a vaccine. Bananas provide an easy means for delivering

a vaccine (especially to children) without the need of a trained medical professional.

## Conclusion

There are many examples of transgenic organisms with extensive uses. It can be concluded that transgenic animals have revolutionized the field of Modern Biotechnology because of their tremendous applications and opened the door for curing complex genetic diseases. Genetically modified crops also have been able to raise the hopes for improving the quality of life of humans.

## Synonyms

[Genetic translocation](#); [Chromosomal translocation](#)

## Definition

A translocation is a chromosomal ability, in which chromosome part breaks down and reattaches with another chromosome. It is easily quantified by the evaluation of the karyotype of the affected cells. Chromosomal translocation usually observed in the case of leukemia and other cancers.

## Introduction

Translocation is a chromosome aberration in which a part of a chromosome breaks and reattaches to the different chromosomes. Chromosomal translocation can be identified by analyzing the karyotype of the affected cells. Translocation was first cytologically reported in the late nineteen and early twenty centuries as a novel chromosome that predominantly present in tumor cells. It can be easily observed through cytogeneticist during karyotype study, which is an ordered arrangement of an individual's metaphase chromosomes. It is commonly reported in cancerous cells, and sometimes

produces oncogene that is accountable for malignant transformation (Aplan et al. 2005). Translocation in humans is linked with many disorders such as mental retardation, infertility, and cancer (Santos et al. 2000).

## Characteristics of Translocation

- Chromosomal translocation is a result of unusual rearrangement of chromosomes.
- It is involved in the generation of a novel chromosome.
- It alters the size of the chromosome as well as the position of the centromere.
- Translocation requires the break down of double-strand DNAs at two different places.
- It occurs many times during the evolution of species and provides help in the identification of closely related species.
- Translocation is mostly associated with a negative consequence such as nut and rarely provides organism adaptation advantage.

## Types of Translocation

Translocation is generally categorized as balance and imbalance translocation. However, it can also be classified as reciprocal, nonreciprocal, and Robertsonian translocation (Fig. 1).

- Reciprocal translocation:** It is an interchange of chromosomal parts between two nonhomologous chromosomes which provides a new linkage relation. Reciprocal translocations are usually harmless and are also transmitted to the next generation. The incidence of reciprocal translocation is 1 in out of 500 to 625 in new-born human (Griffiths 1970).
- Nonreciprocal translocation:** It is one-directional transfer of chromosomal segment to another chromosome. Furthermore, this may drastically alter the chromosome size and position of its centromere (Rezaei et al. 2020).
- Robertsonian translocation:** This is a widespread type of translocation found in humans

**Translocation, Fig. 1** Schematic representation of the different type of chromosomal translocation. (a) Reciprocal translocation, (b) nonreciprocal translocation, and (c) Robertsonian translocation

with the frequency of 1 out of every 1000 babies born. This type of translocation typically found in acrocentric chromosomal, in which the long arm of a particular type of chromosome fused with another chromosome (Poornima et al. 2020; Watson 2018; Hasanzadeh-Nazar Abadi et al. 2014). The acentric chromosome in human DNA are chromosome 13, 14, 15, 21, and 22 undergo there is some characteristic Robertsonian translocation such as:

- Chromosome 13 translocate with chromosome 21
- Chromosome 14 translocate with chromosome 21
- Chromosome 15 translocate with chromosome 21
- Chromosome 21 translocate with chromosome 22

(d) **Balance and unbalance translocation:**

Translocation further may be classified as balance and unbalance translocation. In balance translocation, the exchange of material is without extra or missing genetic information, and there is no alteration in the functionality of the genes. Example of balanced translocation between chromosomes 1 and 11 associated with the decline of the white matter integrity frontal commissural of the brain (Thomson et al. 2016). Additionally, a balanced  $t(1;11)$  translocation was first defined as a single locus significant risk factor that concerns with several psychiatric disorders. It is a rare genetic variation which is the result of chromosomal translocation and can provide help to elucidate the pathophysiology of brain disorders. The translocation involved in the formation of significant linkage with the clinical phenotype that comprised of several brain disorder such as schizophrenia, bipolar disorder, and major depressive disorder.

On the other hand, in unbalanced translocation, the exchange of chromosomal material is unequal resulting in the addition or loss of the gene in the genetic material.

## Role of Translocation in Human Disease

There are several human diseases in human that are the result of chromosomal translocations (Table 1). Some of them are discussed below:

- (a) **Cancer:** Translocation results in disruption or dysregulations of normal gene function. These genomic rearrangements by translocation are considered as the primary cause of several cancers. The research from the last few decades reported that clinical cytogenetics have been able to identify specific point of chromosomal breakdown that is responsible for various cancers as leukemia, lymphoma, as well as sarcoma. Usually, all translocation observed in cancer occurs in somatic cells, and therefore translocations are nonheritable. Chromosomal translocation is the hallmark of cancer, and the mechanism involved in this event needs a clear

**Translocation, Table 1** List of diseases associated with chromosomal translocation

| S.No. | Disease                      | Chromosomal translocation                                             | References            |
|-------|------------------------------|-----------------------------------------------------------------------|-----------------------|
| 1.    | Down syndrome                | Extra 21 chromosome may be attached to the 14 or 13,15,22 chromosomes | Prusti et al. (2014)  |
| 2.    | Schizophrenia                | 1(1;11) (q42.1;q14.3)                                                 | Doyle et al. (2015)   |
| 3.    | Malt lymphoma                | 1(11;14) (q13;q32)                                                    | Li et al. (1999)      |
| 4.    | Synovial sarcoma             | t(X; 18) (p11.2;q1 1.2)                                               | Shipley et al. (1994) |
| 5.    | Acute promyelocytic leukemia | t(15; 17) (q22;q21)                                                   | Liu et al. (2020)     |
| 6.    | Myxoid liposarcoma           | t(12;16) (q13;p11)                                                    | Son et al. (2012)     |

distinction between the causative risk factor and its correlative. Hogenbirk reported chromosomal translocation risk is not related to promoter stalling (Spt5), transcriptional activity, or off-targeting activity of the activation-induced cytidine deaminase (Hogenbirk et al. 2016).

- (b) **Brain disease:** A rare genetic variant that is the result of balanced translocation can help to elucidate the pathophysiology of brain disorders. A balanced translocation t(1;11) is a significant risk factor for psychiatric disorders, including schizophrenia, bipolar disorder, and recurrent major depression. Additionally, this translocation affects the structure and function of the prefrontal and temporal region of the brain. Translocation leads to reduce thickness of the cortex in the left temporal lobe that is correlated with the psychopathology and positive psychotic symptom severity (Klar 2004).
- (c) **Infertility:** Chromosomal translocation is frequently associated with male fertility. Infertility means incapability to perceive after at least 1 year of unprotected intercourse. The frequency of infertility is 15–20% in couple in their reproductive year. Male infertility is a result of reciprocal balanced translocation t (10;19) (q11.2; q13.4) was observed in oligozoospermic infertile men with no Y-chromosome microdeletions (Harton et al. 2014; Kara et al. 2014).

## Application of Translocation

Translocations are primarily involved in the origin of the new chromosome by transfer of the segment

of chromosome to the nonhomologous chromosome or the other site of the same chromosome. Translocation can be easily observed when scientist tries to compare the genome of the closely related species, and it was observed multiple times during evolution. Usually, translocation is associated with a negative consequence such as several psychiatric disorders, cancer, and infertility, but rarely translocation helps in the adaptation of species in a new environment. Translocation can be easily evaluated using the molecular probe and provides a unique insight into the molecular origins of various diseases, including psychiatric disorders.

## Transposition

Olga Lazareva

Drake University, Des Moines, IA, USA

## Synonyms

[Relational learning](#)

## Definition

Transposition is a form of relational learning in which a learned relational response (e.g., smaller) transfers to a novel pair of stimuli after a simultaneous stimulus discrimination training.

## Introduction

The first transposition experiment has been designed by Wolfgang Köhler (1918/1938). In these experiments, chickens and chimpanzees

were presented with a two-alternative simultaneous discrimination in which a response to a darker shade of gray was not reinforced and a response to a lighter shade of gray was reinforced (or vice versa). Once the original discrimination was learned, the subjects were given a choice between the original, light shade of gray and a novel, still lighter, shade of gray. Köhler proposed that learning to respond to a specific shade of gray (*absolute responding*) should result in a preference for the original gray shade; however, learning to respond to the relationship between the two shades (*relational responding*) should produce a preference for a novel shade of gray despite the presence of the previously reinforced stimulus. Both chickens and chimpanzees indeed selected the novel shade on over 70% of the trials. Köhler termed this behavioral result transposition – just as the notes of the melodies do not change their relation to each other when the melodies are transposed to different keys, the learned relation does not change when the new stimuli are introduced.

### Associative Account of Transposition: Spence (1937)

In an elegant theoretical account, Spence (1937) proposed that a seemingly “relational” behavior

in Köhler’s transposition experiment could be explained in terms of reinforcement history. The three simple assumptions behind Spence’s discrimination theory are illustrated in Fig. 1. (1) A reinforced stimulus, or an S+ (S2 in Fig. 1), develops an excitatory gradient (indicated by a dashed line) that gradually declines as the stimuli become increasingly dissimilar from the S+. (2) A nonreinforced stimulus, or an S– (S1 in Fig. 1), develops an inhibitory gradient (also indicated by a dashed line). (3) A response to any stimulus along the sensory dimension is predicted by the postdiscrimination stimulus generalization gradient (PDG) obtained as a sum of an excitatory gradient and inhibitory gradient: The higher the resulting associative value of the stimulus, the greater the preference for that stimulus in the choice test. As Fig. 1 shows, the resulting PDG produces a positive *peak shift* away toward an even larger, novel stimulus S3; a comparison of the resulting associative values suggests a preference for a novel, relationally correct S3 instead of previously reinforced stimulus S2. Although first posited theoretically, the existence of peak shift has been confirmed experimentally providing a striking confirmation of Spence’s theory (Blough 1975; Hanson 1959; Honig 1962; Honig and Urcuioli 1981).

**Transposition, Fig. 1** Hypothetical excitatory and inhibitory gradients (*dashed lines*) and postdiscrimination generalization gradient (*full line*) illustrating predictions of Spence’s (1937) discrimination theory after training with an S2+ S1– discrimination. Vertical lines illustrate the location of previously reinforced stimulus S2, previously

nonreinforced stimulus S1, and a novel stimulus S3. Note that the postdiscrimination generalization gradient indicates “relational” choice in a pair S2–S3 due to the shift of the peak in the postdiscrimination stimulus generalization gradient

However, peak shift is not the inevitable consequence of simultaneous stimulus discrimination. Extensive amount of training sharpens excitatory and inhibitory gradients which reduces or even completely eliminates peak shift (Gerry 1971; Migler and Millenson 1969; Terrace 1966). In addition, the S+ and S− that are located far from each other often fail to produce peak shift even without overtraining (Derenne 2006; Hanson 1959; Thomas et al. 1991). In other words, under certain circumstances PDG will not predict a “relational” response to the novel pair (see Lazareva 2012 for a review).

### Intermediate-Size Transposition

In a different version of transposition experiment, subjects are trained to select a middle out of three stimulus values (for example, S1− S2+ S3−) and then presented with a novel trio comprising at least one novel stimulus (for example, S2-S3-S4); this design has often been termed an intermediate size problem. As Fig. 2 illustrates, Spence’s approach does not predict a “relational” choice in this novel trio, instead suggesting a preference for a previously reinforced stimulus. In line with this prediction, many species (e.g., pigeons, rats, rhesus monkeys, turtles) have

shown either no preference or preference for a previously reinforced stimulus in an intermediate-size problem (Brown et al. 1959; Laverty et al. 1969; Spigel 1963; Zeiler 1965). However, other species (e.g., chimpanzee, rhesus monkeys) have been found to display a clear preference for a middle value in a novel trio of stimuli (Gentry et al. 1959; Gonzalez et al. 1954).

### Multiple-Pair Transposition

Transposition designs that utilize multiple stimulus pairs during training pose additional challenges for associative account of transposition (Johnson and Zara 1960; Lazareva et al. 2005, 2008, 2014; Marsh 1967; Sherman and Strunk 1964). Intuitively, it is plausible to assume that multiple instantiations of the same relational rule will lead to a stronger relational learning. On the other hand, the PDGs produced by multiple-pair training frequently do not predict this outcome.

Consider an example depicted in Fig. 3 in which pigeons were trained to select a smaller of the two circles after one-pair, two-pair, and three-pair training (Lazareva et al. 2008). During testing, all pigeons were presented with the novel testing pairs S4-S5 and S5-S6. As the left panel of the Fig. 3 illustrates, the PDG predicts no

**Transposition, Fig. 2** Hypothetical excitatory and inhibitory gradients (*dashed lines*) and postdiscrimination generalization gradient (*full line*) illustrating predictions of Spence’s (1937) discrimination theory after training with an S1− S2+ S3− intermediate-size discrimination. *Vertical lines* illustrate the location of previously reinforced and

nonreinforced stimuli, as well as the location of the novel stimulus S4. Note that the resulting gradient does not predict correct choice of the middle stimulus S3 in a novel trio S2-S3-S4; instead, it suggests a preference for the previously reinforced stimulus S2

**Transposition, Fig. 3** Schematic representation of experimental design in the small circle condition presented in Lazareva et al. (2008), together with the examples of theoretical excitatory and inhibitory gradients (dashed

lines), the derived postdiscrimination generalization gradient (smooth line), the testing pair accuracy predicted by the postdiscrimination stimulus generalization gradient and the obtained accuracy produced by pigeons

strong preference for either stimulus after one-pair training as the distance between training and testing stimuli is too large for substantial generalization to occur. After two-pair training (middle panel of Fig. 3), the PDG predicts the preference for the “relationally incorrect” S5 in the pair S4-S5 and no strong preference in the pair S5-S6. After three-pair training (right panel of Fig. 3), the PDG predicts “relationally incorrect” choice of a larger stimulus in both testing pairs. Despite these predictions, pigeons increasingly prefer a smaller, “relationally correct” stimulus in both testing pairs as the number of training pairs increase. These and other similar findings led us to propose a three-component model of transposition that describes subject’s behavior as a result of joint influences of generalized associative strength and relational learning (Lazareva et al. 2014).

## Conclusion

Historically, research on transposition has generated substantial body of empirical evidence and theoretical development (see Lazareva 2012; Reese 1968; Riley 1968, for reviews). Together

with the recent research, the evidence suggests that animals indeed can respond to relations in a transposition task although their behavior can be moderated by the prior history of reinforcement, especially after one-pair training. In contrast, multiple-pair training tends to generate robust relational learning and transfer.

## Definition

Trap building is a method by which predators catch prey through the use of a forged structure.

Trap building is a method by which predators catch prey through the use of a forged structure. Trap building is evident in many animals, primarily invertebrate species and humans, that have separately converged on trap building as a specialized form of hunting. There are two evolutionary routes to building traps. Humans demonstrate the “big-brained” route to building traps whereas other trap-building animals demonstrate the “small-brained” route (Hansell, 2007). Humans use collected materials and behavioral flexibility to construct traps that catch prey in water, land, and air, whereas other animals exhibit species-specific trap designs that rely on simple and relatively inflexible construction behaviors and, often, self-secreted materials. Despite the many differences between the trap building of humans and other animals, similarities in nonhuman and human trap types are evident, suggesting there are a limited number of good solutions to the problem of catching prey by trapping.

Spiders build traps via web-making. The orb web spider (*Araneus diadematus*) constructs a spiral web that has a specific capture thread placed on a radial array of threads (Zschokke, 1996). Orb web spiders use a consistent set of tactics in variable sequence to construct a seemingly complex design. When an orb web spider is isolated from birth, it will still construct a web (Zschokke, 1996). *Zygiella x-notata* is a spider that uses a slightly different orb design and rests at the edge of the web where it can hide from unsuspecting prey (Hansell, 2007). Any disturbance to the web causes a vibration, prompting the *Zygiella x-notata* to rush out and kill the prey. Spider webs are traps tailored to capture a particular prey and some flying insects, like butterflies and moths, have evolved the anti-capture countermeasure of detachable scales. An evolutionary arms race between predator and prey is also evident in the trap building of the bolo spider (*Mastophora hutchinsoni*). The bolo spider is a master moth-catcher, using chemicals that mimic female moth sex attractant signals to lure male moths into the web (Haynes et al., 2002). Spiders demonstrate

species-specific web design and their trap-building behavior is highly specialized, genetically determined, and inflexible. The silk created by spiders is an example of a self-secreted building material. Silk is preferable to mucus for building nets because it is more durable, stronger, can be spun on land or in water, and it recovers its shape after being deformed (Hansell, 2007).

It appears that, in many trap-building species, natural selection has modified mucus secretions that formerly assisted with locomotion to trap prey. *Praxillura maculata* is a burrow-dwelling marine worm that uses mucus to build a net to capture fine particles suspended in water (Hansell, 2007). *Gleba cordata* is a mid-water, oceanic snail with no shell that feeds on plankton. To capture plankton, this species secretes and deploys a finely meshed, sticky mucus net that can be one-third of a meter or more across (Hansell, 2007). *Oikopleura dioica* is a small, tadpole-like creature that builds a capsule of mucus as both a dwelling and a trap, capturing plankton as prey (Hansell, 2007). A multipurpose structure like the dwelling/trap of the *Oikopleura dioica* does not require imagination or behavioral flexibility; thus, complex architecture is possible with a small brain and efficient use of materials. These behaviors are likely highly canalized. For example, Klokócovnik and Devetak (2014) demonstrate that non-pit-builder antlions show less stereotypic predatory behavior compared to pit-building antlions.

The burrowing owl is an example of an animal that uses bait to attract prey, although the owl's burrow may not qualify as a trap. The burrowing owl gathers cow dung and places it at the burrow entrance to attract dung beetles and other insects as prey (Smith & Conway, 2007). The built structure of the burrowing owl is not a trap because direct predation is the method employed to capture the insects. The prey is not trapped by the dung or by the burrow. By this definition, there are no birds that build traps (Hansell, 2007).

## Trap-Table

Alex Taylor and Patrick Neilands  
The University of Auckland, Auckland,  
New Zealand

Causal reasoning refers to the understanding of how and why one event can cause another. A key part of causal reasoning is the ability to reason about invisible forces such as gravity or weight rather than simply relying on perceptual cues (Limongelli et al. 1995; Reaux and Povinelli 2000). For example, birds may drop stones to collapse a platform baited with food by reasoning that the force exerted by the falling stone will

collapse the platform (von Bayern et al. 2009). However, an alternative explanation is that they learn to solve problems through associative learning by mentally pairing behaviors or cues with reward. In our example of stone-dropping birds, the animals may have simply learnt, through trial and error, a procedural rule of “if-an-object-is-dropped-onto-the-platform-it-will-collapse” without having any understanding of *why* dropping the stone collapses the platform.

The trap-tube test was designed by Visalberghi and Limongelli et al (1995) to distinguish between these types of competing explanations. In the typical trap-tube task, food is placed in a horizontal tube with a trap (a hole with a base which food cannot be retrieved from). In order to obtain the food, the animal must extract it in a direction that avoids the trap. A causal account of an animal learning to solve the task would be that the animal develops an understanding that if it pushes the reward over the hole, gravity (an unobservable force) will cause the reward to drop into the trap. An associative account of such success is that over the course of repeated trials, through trial-and-error, the animals develop a procedural rule such as “insert-the-tool-into-the-end-furthest-from-the-reward.” As both accounts can explain success in a trap-tube task, Limongelli and Visalberghi designed an ingenious control where the tube was inverted, making the trap non-functional. If an animal had used causal reasoning, it should no longer avoid the trap, as it would understand that objects cannot fall up. In contrast, if the animal had used associative learning, the trap would be an aversive cue, as its position had in the past predicted failure, and so the animal would continue to avoid the trap.

In 1994 and 1995, Limongelli and Visalberghi presented the trap-tube task (Fig. 1) to capuchin monkeys and chimpanzees. One out of four capuchin monkeys learned to extract the food out of the tube while avoiding the hole. However, in the inverted tube control condition, the one successful capuchin continued to avoid the trap. This led the authors to conclude that the capuchin monkey had solved the trap tube using a procedural rule of inserting the stick in the opening furthest from the reward. As the trap was in the center of the

### Trap-tube Test

### Inverted Control

tube, inserting the stick in the furthest end from the food and pushing would allow the capuchin to avoid the trap. When two out of five chimpanzees learned to solve the trap-tube tasks, the authors attempted to control for this procedural rule by running a second experiment where the trap was placed on one side of the tube or the other. The chimpanzees passed this control, leading the authors to conclude that, unlike the capuchins, the chimpanzees were using causal understanding of the task in order to obtain the reward (Limongelli et al. 1995). However, Povinelli critiqued the authors’ interpretation, arguing that there were several other associative rules that chimpanzees may have learned, such as “push-the-reward-away-from-the-trap,” which could not be ruled out because the inverted-trap condition had not been run. Povinelli and Reaux (2000), therefore, ran the trap-tube task with chimpanzees but included the inverted-trap condition and several other novel conditions where inserting the tool in the end furthest from the reward was not necessary for success. They found that the chimpanzees failed these controls and so concluded that the chimpanzees were relying on procedural rules to solve the trap-tube task.

## Critique of Early Trap-Tube Experiments

Whereas Povinelli’s results were consistent with the hypothesis that chimpanzees do not use causal

reasoning to solve the trap-tube task, this conclusion relies on the interpretation of chimpanzees’ failure in the inverted tube control condition. Such interpretation of negative results is difficult because it is possible that the chimpanzees used causal reasoning but failed the control conditions for other reasons. This issue became more pertinent after Tebbich and Bshary (2004) reported that one out of six woodpecker finches (a tool-using bird from the Galapagos islands) was able to solve the trap-tube task and also pass the inverted-trap condition. A key difference in the finches’ and chimpanzees’ tasks was that the finches could use their tool to pull the reward out of the tube, whereas the chimpanzees could only use the tool to push the reward. Mulcahy and Call (2006) allowed great apes to pull the food from the tube and found that the apes solved the trap tube much faster than in past studies and then ignored the inverted trap. The authors then presented the apes with the standard trap tube setup where the apes could only push and found they now failed, confirming that earlier results had been confounded by subjects only being able to push the reward (Mulcahy and Call 2006).

As well as methodological issues with the interpretation of prior results, Silva and colleagues tested humans’ performance in the trap-tube task and suggested that, despite its intuitive logic, there were conceptual flaws with the inverted trap-tube condition. Although the humans were better at solving the task (almost all of the humans involved solved it rapidly), humans tended to avoid the trap even when it was inverted. As it is unlikely that the humans did not understand the causal structure of the task, the authors argued that a failure to show indifference in the inverted trap condition was not sufficient to rule out causal accounts of animals’ performance at this task (Silva et al. 2005).

## The Creation of the Trap-Table Task

In light of these methodological and conceptual critiques, more recent studies have attempted to reduce task demands and have used transfer tasks as additional control conditions. Task demands

were reduced by either removing tools or having tools already inserted so that participants did not need to manipulate the tools to obtain the reward. Transfer tasks involve a subject learning to solve the trap tube task before being presented with a transfer task, a novel task, in which arbitrary perceptual cues are changed, but the causal structure remains the same across both tasks (Martin-Ordas et al. 2008; Seed et al. 2006; Taylor et al. 2009). If the subject is sensitive to the functional properties of the initial task, they should be capable of transferring this understanding to novel tasks. However, if the subject has learned to solve the initial task through associative learning, reliance on arbitrary perceptual cues should prevent the animal from transferring procedural rules effectively, leading it to fail the transfer task.

One influential transfer task is the trap-table task (Fig. 2). In a trap-table task, the subjects must choose between using a rake to retrieve either one reward located behind a trap or another reward located on a continuous surface. This task presents the same conceptual challenge as a trap-tube task, namely avoid pulling the food into a hole, while presenting the animals with a very perceptually distinct set of apparatuses. Thus, in order to successfully transfer the solution of the trap-tube task to the trap-table task, the animals must have learned the functional properties of the trap-tube rather than simply depending on arbitrary perceptual cues.

In the initial trap-table task (Povinelli and Reaux 2000), the chimpanzees were presented with a table that was divided into two halves. On each half of the table, a rake was placed such that pulling on it would pull a reward towards the apes. However, there was a hole on one half of table and so pulling in the rake on that side of the table would result in the reward falling down the hole. The other half of the table was one continuous surface and so pulling on that reward would result in the individual successfully retrieving the reward. One chimpanzee appeared to successfully transfer the solution from the trap-tube experiment to the trap-table experiment, choosing to pull the correct rake significantly more often than chance and also on the first trial. However, considering that the other five chimpanzees failed to solve the trap-table task, Povinelli argued that this success may reflect a preexisting bias of the chimpanzee to prefer the painted continuous surface (a perceptual cue) rather than reflecting a causal understanding of the task.

However, while the poor performance of the apes in the trap-table task is suggestive that the chimpanzees have not understood the functional properties of the trap-tube task, the possibility remains that unrelated task demands were causing the apes to fail and, therefore, potentially masking the apes' causal understanding of the task. In order to control for this possibility, Girndt et al. (2008) tested several species of ape with the

**Trap-Table, Fig. 2** Diagram of a crow solving a trap-tube task (c) and a trap-table (d). While perceptually distinct, the causal structure of both tasks is the same. (Adapted from “Is there a link between the crafting of tools and

intelligence” by Taylor & Gray, 2014. *WIREs Cognitive Science*, 5(6), 696. Copyright 2014 by Wiley Online Library)

original version of the trap-table task and a modified version where the apes had to insert a single rake to obtain the food (rather than choose between two rakes). The apes' performance was much better in the modified trap-table task than in the original, with 80% of subjects solving the task on their first trial. In order to test whether modifying the trap-table task could lead to improved solution transfer, another experiment (Martin-Ordas et al. 2008) presented half of the chimpanzee sample with a trap-tube experiment and the other half with a modified trap-table experiment. After solving one task, the apes were presented with the second task. Although the apes were capable of learning to solve both tasks, performance in the first task did not predict success in the second task, suggesting that the apes were not transferring a solution from one task to the other.

In contrast to the performance of the apes, New Caledonian crows seem capable of transferring their solution from the trap-tube task to trap-table tasks. Taylor et al. (2009) tested six New Caledonian crows with a trap tube test. Three of the six crows learned to solve the task and proceeded to pass a series of transfer tasks where arbitrary cues were successively removed and a further transfer task where they were presented with a trap-table task. In the trap-table task, the crows successfully chose to use a tool to pull a reward located on a continuous surface while avoiding a reward located behind a trap.

While these results may suggest that corvids are using causal understanding to solve the trap-tube task while apes are not, apes are capable of passing other transfer tasks. For example, instead of using a trap table, Seed et al. (2009) modified the trap-tube task by presenting apes with trap-box tasks where the apes could retrieve the food using their fingers rather than a tool. Reducing the task demands improved the chimpanzees' performance and all eight successfully solved two trap-box tasks (Task A and Task B). Six of the apes then took part in two transfer tasks, where, as in past studies with rooks (Seed et al. 2006), there was no consistent cue that predicted success (Task C and Task D). Two individuals solved tasks C and D, ruling out the use of associative learning

and suggesting that apes too may be using causal understanding to solve these problems.

## Conclusions

The performance of corvids and apes in recent trap table tasks and other transfer tasks suggests that they are using more than associatively learned procedural rules to solve the trap-tube task. Rather they seem to learn the functional properties of the task and can use this knowledge to solve novel problems. However, this is not sufficient to prove that animals reason about unobservable forces such as gravity. It is possible that these animals solved these tasks by attending to the observable features of the task which are functionally relevant (such as the need for surface continuity and the inability of objects to pass through solid surfaces) without reasoning about *why* these features are causally relevant (Seed et al. 2006, 2009; Taylor et al. 2009).

Whereas some, such as Povinelli (Povinelli and Reaux 2000), argue that this lack of evidence supports the assertion that nonhuman animals are incapable of reasoning about unobservable forces, this lack of evidence more accurately represents limitations of the trap-tube and trap table paradigms. Whereas animals' performances on transfer tasks such as the trap-table task tell us something about what they have learnt (namely, the functional properties of the task), it is not informative about how they have learnt this (Seed et al. 2009). Therefore, while the trap-table has extended our understanding of animal problem-solving, novel approaches are required to probe whether animals reason about unobservable forces.

Recently, one possible alternate approach has been developed that can distinguish between attention to observable features or interactions and an understanding of unobservable forces. von Bayern et al. (2009) demonstrated that New Caledonian crows, who initially could not solve a task where they had to drop a stone to collapse a platform, learned to do so after receiving experience of collapsing platforms with their beaks. This suggested that the crows might have understood that force

above a certain level needed to be applied to the platform to make it trigger, leading them to drop a heavy object (the stone) when the platform became out of reach of their beak. An alternative explanation is that the crows understood that an observable interaction, contact, needed to occur between the platform and another object (either beak or stone). Thus, while these results suggested that the crows were capable of reasoning about unobservable forces, the contact hypothesis is an alternative explanation. In a follow-up experiment, Neilands et al. (2016) demonstrated that after receiving experience collapsing the platform with their beaks, New Caledonian crows did not discriminate between dropping heavy or light blocks (which were too light to trigger the platform) and so seemed to be using the concept of contact to solve the problem. Although the crows failed, the methodology itself offers much promise for testing for causal reasoning. If a naïve animal drops only heavy objects after being given experience of pushing the platform down with their body, it would provide strong evidence that animals can reason about unobservable forces, provided, of course, that controls show the subject had no preexisting bias for dropping heavy objects.

## Trap-Tube Problem

Elisabetta Visalberghi

Institute of Cognitive Sciences and Technologies,  
National Research Council, Rome, Italy

## Definition

**Trap-tube problem.** This task investigates causal reasoning in the physical domain. It consists of a transparent horizontal tube containing a reward

that can be obtained by pushing it out of the tube with a stick. The trap tube has a hole on its bottom surface such that if the reward is pushed above the hole, it falls through the hole into a trap where it cannot be reached. Thus, errors are penalized. The tube transparency allows experimenter and subject alike to view how the tool affects the reward movement throughout the tube and through the hole. In this task an adult human performs correctly on the basis of her/his causal reasoning about the affordances of the tube and the trap. In contrast, other species can be successful by using simpler associative strategies, but control procedures can rule them out.

## Introduction

Success in tasks requiring flexible tool using behaviors appears to imply the ability to understand the relationship between means and ends and the effects produced by acting with the tool. When an animal closely resembling humans, such as a monkey, uses a tool to solve a problem, the human observer is prompted to believe that the processes underlying solution are the same, or almost the same as if a human were solving that problem. The trap-tube task has demonstrated that this might not be the case.

## The Tube Task

The logical antecedent of the trap tube was the tube task, a problem requiring the use of a stick to dislodge an out-of-reach reward positioned in the middle of a transparent tube (Fig. 1, above panel). The tube task investigated how capuchin monkeys (*Cebus apella*, now *Sapajus* spp.) (recent molecular analysis has revealed that capuchin monkeys, formerly identified as the single genus *Cebus*, are two genera, with the robust (tufted) forms (including *apella*, *libidinosus*, *xanthosternos*, and several other species) now recognized as the genus *Sapajus* and the gracile forms retained as the genus *Cebus* (Lynch Alfaro et al. 2012)) deal with the challenges of modifying tools to fit the tube by selecting tools from among

**Trap-Tube Problem, Fig. 1** The tube task (above) and the complex conditions (below). (Redrawn by Luca Antonio Marino from Visalberghi and Limongelli (1994))

several presented (Visalberghi and Trinca 1989) and, subsequently, to compare capuchins' performances to those of other primate species (chimpanzees, *Pan troglodytes*; bonobos, *Pan paniscus*; orangutans, *Pongo pygmaeus* Visalberghi et al. 1995; children, Visalberghi 2000).

Capuchins proficient at pushing a reward out of a transparent tube with a stick were tested in three new conditions in which the provided object(s) had to be modified or combined to become a functional tool and dislodge the reward from the tube (Visalberghi and Trinca 1989, see below panel in Fig. 1). In one condition, the sticks were so short that two of them had to be inserted one behind the other inside the tube to move the food far enough for the monkey to reach it. In another condition, the object (a bundle of thin canes held together by tape) was too large in diameter to fit into the tube. In the third condition, the stick had thin pieces of dowel (which could be pulled out or broken off) inserted transversely at each end so that the ends of the stick could not enter the tube.

The capuchins solved all conditions within a few minutes. Despite their success, they made many attempts to use the provided object without modifying it or to use parts of the object (e.g., the tape, a splinter) that did not have the necessary properties (e.g., rigidity, length) to displace the food from the tube. Over the ten trials in each condition, the number and/or nature of errors produced by each monkey decreased only slightly. However, when these same capuchins were given

16 choice trials among objects that did not afford insertion or would not reach the food (one too thick, one too short, and one with a transversal block at each end) and one object of appropriate diameter and length, all subjects learned to select the only appropriate object far more often than would be expected by chance (Visalberghi 1993). Thus, capuchins learned by association what features of the objects, surfaces, and actions were most important for success.

In the above tests, each subject eventually was always successful since errors were penalized only in terms of time necessary to achieve success. Without capuchins demonstrating a limited understanding of their own success (and failure), the trap-tube experiment would never have been conceived (Visalberghi and Limongelli 1994, 1996). The trap tube aimed to explore capuchins' appreciation of tools affordances and functioning, of "why" and "how" an event leads to another, an approach that closely reminiscent of the pivotal work of Köhler (1925/1976).

## The Trap-Tube Task

The trap-tube apparatus designed by Visalberghi and Limongelli (1994; hereafter labeled VL-trap-tube whenever necessary to distinguish it from other trap tubes which do not have the same features and challenges) consisted of a transparent horizontal tube containing a reward that can be obtained by pushing it out of the tube with a stick. The trap tube has a hole on its bottom surface such that if the reward is pushed above the hole, it falls through the hole into a trap where it cannot be reached (see Fig. 2). The food reward was randomly placed on the right and on the left side of the hole. To get the food, the capuchin had to insert the stick into the side of the tube from which it could push the food away from the trap. Thus, the subject must take into account the outcome of its action with the stick on the movement of the food (toward or away from the trap) and avoid moving the food over the trap. In this task, the subject 50% success can be achieved by systematically inserting the stick into the same end of the tube or by inserting it into one of the two ends

**Trap-Tube Problem, Fig. 2** The trap-tube task, as in Visalberghi and Limongelli (1994), consists of a transparent tube with a hole in its center and a trap underneath it. The top panel shows an example of wrong insertion of the stick: pushing the stick results in loss of the reward, which falls into the trap. The bottom panel shows an example of correct insertion of the stick: pushing the stick results in retrieval of the reward, which falls out of the tube. (Redrawn by Luca Antonio Marino from Visalberghi and Limongelli (1994))

randomly. Only rates of success higher than chance should be considered as evidence that the subject actively avoids the trap.

Trap avoidance can be obtained either (i) by avoiding the trap through a rule of action based on associative processes (such as push the food away from the trap, or insert the stick from the side farther from the reward) or (ii) by recognizing the outcome of pushing the food into the trap and understanding the underlying causal structure, as humans do. Scientific experiments cannot prove that the subject recognizes the underlying causal structure, but they can rule out parsimonious alternative hypotheses based on associative processes.

## Capuchin Monkeys

Four capuchin monkeys were tested in 14 blocks of 10 trials each. The rate of success was at chance level for three monkeys, whereas that of the fourth subject, Roberta (3 years old), was significantly higher than chance (86%) in the second half of the experiment. A careful analysis of Roberta's behavior demonstrated that she adopted a distance-based rule of inserting the stick in the opening farthest from the reward. Roberta repeatedly looked inside the tube from either side and checked the spatial configuration among stick, tube, and reward. Her behavior seemed to fit the hypothesis that by looking inside the tube entrances, she was estimating the distance of the

reward from them and choosing to insert the stick into the side farther away from the reward. To better explore her comprehension of the trap functioning, Roberta was tested in other conditions in which, regardless in which side of the tube she inserted the stick, she could always obtain the reward (Visalberghi and Limongelli 1994; Fig. 3). Roberta kept using the distance rule (i.e., she inserted the stick from the tube side farther away from the food) even when presented with a trap that was ineffective because the opening had been positioned above the tube (Fig. 3 top left), with a straight transparent tube with no trap (Fig. 3, panel top right), with an opaque trap-tube task (Fig. 3, bottom left), and with a straight opaque tube with no trap (and the reward was placed inside the tube slightly to the right or left of the middle, as was also the case in trials with the trap-tube task, Fig. 3 bottom right).

Generalizing the distance rule to the conditions described above suggested that Roberta was not considering the relevant properties of the trap. However, the generalization of the distance rule was neither “wrong” nor costly, since the reward was always secured. In this respect, it is important to mention that adult humans may also use the same distance-based strategy to determine in which side of the tube to insert the tool when there were no traps or ineffective traps (Silva et al. 2005). Thus, generalization of the distance rule may coexist with an understanding of the functioning of the trap. But, would capuchins abandon the distance strategy if it has a cost, such as losing the reward?

To answer this question, Limongelli et al. (1995) designed a modified trap tube in which the adoption of the distance rule would lead to moving the reward into the trap (Fig. 4); in this modified trap tube, the trap was not centered, and one “arm” of the tube was longer than the other, but the position of the reward inside the tube was as in the trap tube. When tested in 30 trials with the trap-tube condition alternated with 30 trials with the modified trap-tube condition, Roberta used the distance rule regardless of condition, and in the modified trap tube, her rate of success was significantly below chance level. The finding that she did not abandon the distance strategy when costly indicates she did not understand the functioning of the trap tube.

Adult humans anticipate or can imagine the effect of pushing the food with the stick and (simultaneously) the fate of the food when it moves above a hole. Thus, the position of the food with respect to the trap is integral to how we decide where to push the food. Capuchins, even when expert at using sticks to push food from a tube, fail to appreciate the causal relation between their behavior and the food falling into the trap.

### Chimpanzees

The trap tube was also presented to 5 chimpanzees in 14 blocks of 10 trials each. Two of the five subjects solved it above chance level (Limongelli et al. 1995). In the second half of the experiment (Blocks 8–14), their rate of success was significantly higher than chance (Darrell = 90% and Sheba = 99%). To assess

**Trap-Tube Problem,**  
**Fig. 3** Control conditions.

Marino)

**Trap-Tube Problem, Fig. 4** Trap tube as in Limongelli et al. (1995). Above: the trap tube has the trap in the center and the reward positioned on the right or on the left side of the trap. Below: control trap tube with the trap displaced from the center and positioned on the right or on the left

side of the tube and the reward positioned as in the trap-tube task. In the control conditions, trials of the trap tube were alternated with trials with the control trap tube. (Redrawn by Luca Antonio Marino from Limongelli et al. (1995))

whether the successful subjects used a representational strategy (represented beforehand the outcome) or an anticipatory strategy (anticipated failure and changed side of insertion), the number of successful single-insertion trials and the number of multiple-insertion trials were compared. Both subjects mostly used the representational strategy (Darrell = 83% and Sheba = 93%). It is interesting to mention that the successful capuchin mostly performed multiple insertions using an anticipatory strategy (for details see Visalberghi and Limongelli 1994).

To rule out the hypothesis that chimpanzees used the distance rule (as the only successful capuchin in Visalberghi and Limongelli 1994), a control experiment was carried out by modifying the tube so that the trap was not centered and one “arm” of the tube was longer than the other (see Fig. 4). The high rate of success of both chimpanzees in this modified trap-tube task (in which the distance rule is always penalized) ruled out the possibility that a distance strategy could account for success and indicate (but not proven, since experiments cannot prove something but only rule out alternative hypotheses) that the two chimpanzees might have understood the relevant causal relation between their action on the food and the food movement over the hole.

### Children

Children between 27 and 66 months of age were tested in the VL-trap-tube task (Visalberghi and Limongelli 1996). Children under 3 years of age did not figure out a successful strategy, whereas those over 3 years did. The behavior of successful children resembled those of the successful

chimpanzees; typically they looked at the setup (and not into the opening of the tube as the successful capuchin), evaluated the situation, inserted the stick into the correct side of the tube, and pushed the reward out of the tube. Children reached success more quickly than did chimpanzees and spontaneously commented the risk involved in moving the reward over the trap and the necessity to avoid it, or they talked about it if requested (Visalberghi and Limongelli 1996; see also Want and Harris 2001). It is interesting to note that children could solve the tube task in the second year of life, whereas they only solved the trap-tube task much later in the fourth year of life (or, according to Horner and Whiten (2007) who used the VL-trap-tube in social learning experiments, even later at 5–6 years of age). Thus, also for children, solving a tool task is not at all the same as solving the trap-tube task in which errors are penalized and multiple causal relationships between the tool and the tube, the tool and the reward, and the reward and the trap should be taken into account (Visalberghi and Tomasello 1998).

### Other Trap-Tube Experiments

The trap-tube paradigm was later adopted to evaluate the tool-using competences of several non-human species (see the next two sections); moreover, modified trap tubes were used to investigate the ability to learn from others’ mistakes in children (Want and Harris 2001) and social learning in chimpanzees (Horner and Whiten 2007). In some studies the VL-trap-tube task was modified,

for example, by the presence of two traps on the same tube (e.g., Seed et al. 2006), by allowing the subject to rake and/or push the reward out of the tube (Mulcahy and Call 2006), by making the trap opaque (Martin-Ordas et al. 2008), thereby providing some new insight on what the subjects find challenging. It is very unfortunate that these modifications also made the results difficult to compare across studies.

To understand what makes the trap tube difficult and whether subjects could generalize their knowledge across different tasks requiring similar causal knowledge, other tasks with a hole to avoid when moving a reward over a surface were designed. Also in these other tasks, the subjects could develop procedural rules that may or may not be accompanied by an abstract conception of the invariant physical laws (such as gravity) governing the movement of the tool or of the target object. These other tasks assumed to test similar cognitive capacities, such as the trap-table problem (e.g., Povinelli and Reaux 2000), the trap platform and the trap table (e.g., Martin-Ordas and Call 2009). However, this assumption did not seem well supported since the results of tests performed on the same subjects using trap tubes and other paradigms often did not correlate (e.g., Povinelli and Reaux 2000; Martin-Ordas et al. 2008). When Martin-Ordas and Call (2009) looked for correlation among four different tasks, they found no significant correlations between most of the tasks and were particularly struck by the absence of correlation between the trap-platform task and the trap-tube task. The trap tube was also presented in ways that did not require the use of a tool (e.g., Seed et al. 2009). Since the trap tube was designed to evaluate whether a subject that moves a reward into a tube with a trap understands how to use the tool to reach success above chance level, we will only focus on the experiments carried out with trap tubes and a tool to dislodge the reward.

### Nonhuman Primates

Reaux and Povinelli (2000) presented the VL-trap-tube and the inverted VL-trap-tube tasks to chimpanzees at 5–6 years of age and again at 9–10 years of age; they also added a few tool-

biased conditions in which adopting the distance rule when not necessary implied a small additional cost (such as transporting the tool farther, or removing the tool already inserted in the tube; for details see Reaux and Povinelli 2000). Only one subject (Megan) solved the task above chance level at the younger age, and another did so when older (Candy). Both solvers kept using the distance strategy in the tool-biased conditions and, as the capuchin Roberta, when the trap was positioned above the tube.

In sum, only one out of four capuchins (25%) tested by Visalberghi and Limongelli (1994), two out of five chimpanzees (40%) tested by Limongelli et al. (1995), and three out of seven chimpanzees (43%) tested by Reaux and Povinelli (2000) learned to avoid the trap during training or with additional training. These data indicate that having full access to the relevant information concerning how the tool moves the reward out of the tube or into the trap does not make the trap tube an easy problem for either apes or capuchins. Moreover, control procedures indicated that the capuchin and Reaux and Povinelli's (2000) chimpanzees adopted the rule of inserting the stick into the end of the tube farthest from the food, whereas this strategy was ruled out for the two chimpanzees in Limongelli et al.'s (1995). Thus, it is possible that the latter subjects might have had a causal understanding of the problem.

Mulcahy and Call (2006) tested a total of ten apes (five oranges, two chimpanzees, two bonobos, and one gorilla) in a trap-tube width enough to allow the subject to push or rake the reward with the tool and with the trap not at its center (Fig. 5). Results showed that raking was highly preferred over pushing and that three raking subjects (two oranges and one chimpanzees) learned to avoid the trap within 24, 48, and 60 trials. Moreover, they solved with single insertions and did not avoid the trap when nonfunctional (i.e., above the trap). However, none of them was successful when later tested in a trap tube in which only pushing allowed to obtain the reward; the reward was in the middle of this trap tube and its arms were of different length (Fig. 5, bottom). The lack of transfer between trap tubes shows that they were not equal from the apes' point of view and makes

**Trap-Tube Problem, Fig. 5** Trap tube as in Mulcahy and Call (2006). The reward is centered and the trap can be on either side of the tube. The width of the tube allows obtaining the reward by pushing and/or by raking. (Redrawn by Luca Antonio Marino from Mulcahy and Call (2006))

comparisons between the results obtained in the trap tube allowing raking and pushing and in the trap tube allowing only pushing problematic. Note that both raking and pushing are common actions for apes and that apes can control instinctive preferences when necessary (Rosati et al. 2007). Unfortunately, in Mulcahy and Call's (2006) study, no control condition was run to rule out a simpler strategy of solution, such as that the subject might have considered the trap as a cue indicating in which side to avoid raking. Since the traps were in fixed positions, a simple rule as this one could be learned quickly.

Martin-Ordas et al. (2008) presented 2 trap tubes (positioned one above the other) to 20 apes (6 oranges, 6 chimpanzees, 5 bonobos, and 3 gorillas). Seven of these apes were previously tested in the Mulcahy and Call's (2006) trap-tube test, and only one was successful. Each tube had a black/opaque trap whose location was on the right or on the left side of the tube; the location of each tube was the same during the 12 trials of a session and changed across sessions. Within 36 trials, 7 additional apes solved this task by raking; no control condition was run to rule out simpler strategies of solution. According to the authors, the relatively high number of solvers and their fast learning were related to the possibility of raking and the copresence of the two trap tubes. Martin-Ordas and Call (2009) exposed eight apes (three

chimpanzees, two bonobos, two orangutans, and one gorilla) to two trap tubes in a functional condition (in which the reward was at the center, the tube arms were of different length, and a black opaque trap was attached to the tube and connected by a hole, as in Martin-Ordas et al. 2008) and to two control nonfunctional conditions. In the fake nonfunctional condition, the trap was attached to the tube but with no hole connecting the tube with the trap and in the painted nonfunctional condition in which the position of the painted trap was the same as in the functional and the fake conditions. Four apes avoided both the functional and the fake nonfunctional traps, and the other four avoided above chance only the functional trap. None of the eight avoided the painted trap above chance level (though four avoided it in about 50% of the trials). The results showed a mixed picture indicating that at least some apes are able to distinguish between functional and nonfunctional traps; however, it is worthwhile to mention again that avoiding the nonfunctional trap did not have a cost and that also adult humans may generalize in similar conditions (Silva et al. 2005). Interestingly, their best four apes did also solve the trap-tube task in a previous study (Martin-Ordas et al. 2008). Unfortunately, a trap tube not allowing raking behavior was not presented to these apes. In the above studies (for an exception, see Mulcahy and Call 2006), the performance of the four ape species did not differ.

In conclusion, all the trap-tube studies described above indicate that this problem is difficult and only a limited number of apes succeeded. The successful ones (Limongelli et al. 1995; Mulcahy and Call 2006; Martin-Ordas et al. 2008; Martin-Ordas and Call 2009) acquire some knowledge about the causal relations between the trap, the reward, and the tool they can use to obtain the reward. However, this knowledge is often not robust enough (i) to establish analogies across tasks that appear (to us) all related to what causes a trap to be effective, (ii) to prevent generalizations in situations in which the trap is not effective, and (iii) to allow success when the experimental setup requires different actions (well within the subject's repertoire).

More studies relying on the use of the same apparatus and procedure would have been necessary to clarify the competence of apes in this task.

## Birds

Tebbich and Bshary (2004) presented six woodpecker finches (*Cactospiza pallida*) with a trap-tube task (see Fig. 5) in which the solution could be obtained either by inserting the tool at the end nearest to the trap and pushing the reward or by inserting it at the end furthest to the trap and raking the reward. Most of the birds raked the reward toward themselves, and one solved the task after 100 trials and did not generalize to the inverted trap-tube condition. Unfortunately, no control condition to rule out the distance strategy when raking was carried out.

When non-tool-using bird species were tested, as rooks (*Corvus frugilegus*; Seed et al. 2006) and parrots (*Nestor notabilis*, *Ara chloroptera*, *Cacatua sulphurea*; Liedtke et al. 2011), the apparatus did not require the use of the tool. The bird had just to push or pull the stick attached to two discs sliding inside the tube (retaining the reward between them). Since dealing with traps without a tool “may not impose the same cognitive demands as the original trap-tube task” (Tebbich et al. 2007, p. 230) and also for chimpanzees is less

challenging than dealing with traps and tools (Seed et al. 2009), these experiments will not be discussed.

Six wild New Caledonian crows (*Corvus moneduloides*) were tested in two tool problems of similar structure: the two-trap tube (see Fig. 6) in which there were an effective trap (with a base) and an ineffective trap (without a base) and in the trap table (with a trap embedded into a table that should be avoided) (Taylor et al. 2009a). The three successful New Caledonian crows solved the initial two-trap tube (Fig. 6a) by pulling and often switching side they were probing, after an average of more than 100 trials. Afterward they were tested in three transfer conditions (Fig. 6b–c) designed to rule out the possibility that they had used arbitrary features to reach success in the initial tube (such as the color of the disc (transfer b), the color of the rime (transfer c), and the presence of a trap base that allows the trap to be functional or not (transfer d). They were successful above chance level in the transfers b and c, but not in transfer d. Strikingly, they rapidly solved the trap-table task, while the three other crows that had been unsuccessful in the two-trap tube task did not. Given that the three crows successful in the initial two-trap task continued to succeed when the cues associated with the trap were removed (transfers b and c and the table-trap task), low-level associative strategy of solution

**Trap-Tube Problem, Fig. 6** The two-trap tube experiment, as in Taylor et al. (2009a); (a) the initial two-trap tube and (b–d) the three transfer two-trap tube conditions. The colored discs represent actual colors and solid surface. (b) The left trap was nonfunctional with a transparent solid surface, and the trap tube was placed on a wooden surface.

The arrows show the direction in which the subject raked the reward out of the tube. The asterisks indicate the side of the tube from which the reward can be obtained. (Redrawn and modified by Luca Antonio Marino from Taylor et al. (2009a))

can be ruled out. Moreover, other two alternative explanations for success were ruled out by Taylor et al. (2009b) who demonstrated that New Caledonian crows did possess a predisposition to avoid holes and that their successful crows only avoided the hole when it was in a functional position (i.e., in the bottom of the horizontal tube). Thus, New Caledonian crows appear to have a good understanding of the causal relationship concerning the reward-hole interaction (Taylor et al. 2009a), even if they failed to predict that food would fall out of a tube if they pushed it into the baseless trap.

### Definition

The traveling salesman problem is the task of determining an optimal path through several points and return to the starting point.

### Introduction

“Given a list of cities and the distances between each pair of cities, what is the shortest possible route that visits each city once and returns to the origin city?” The traveling salesman (or salesperson) problem (TSP) is a well-known mathematical problem that was first defined in the 1800s and studied in the 1930s. The task is to connect each of several points (nodes) and return to the origin using the shortest possible path (tour) (see examples in Fig. 1).

Despite the simplicity of the problem's description, solving the TSP is computationally hard. The only known method to solve any TSP between  $N$  nodes is to calculate and compare all possible  $(N-1)!$  tours, which becomes impractical for large  $N$ s. For example, there are 24 potential tours to join five nodes. This number increases over 300,000 when it is required to join ten nodes, putting solutions for 50 nodes or so out of reach of current computing machineries. For these reasons, the TSP has become a classic algorithmic problem in computational mathematics that belongs to the class of NP-complete problems for which the worst case running time for any algorithm increases super-polynomially with the number of nodes. Many algorithms have been developed to find approximations of the optimal tour with reduced computation time. This approach is used in a broad range of applications in logistics, manufacturing, telecommunication, genetics, and neurosciences, to name just a few (Applegate et al. 2007).

Over the past 50 years, researchers in psychological, cognitive, and behavioral sciences have started to exploit the TSP to study perceptual problem-solving, planning, navigation, and spatial cognition in humans and some other animals. The problem is so complex that animals are not supposed to be capable of solving it. Instead, they may use simple decision rules (heuristics) to find efficient tours in a limited time. The questions addressed, procedures used, and results obtained in these researches have varied considerably across studies.

The experimental approach falls into two broad versions of the TSP: a visual (two-dimensional)

### Traveling Salesman,

**Fig. 1** Hypothetical examples of solutions to traveling salesman problems (TSPs) in a randomly generated array of seven nodes. (a) Shortest possible tour, (b) random tour, and (c) tour resulting from the nearest neighbor strategy in a closed TSP starting and ending at A. (d) Shortest possible tour in an open TSP starting at A and ending at B

TSP and a navigational (three-dimensional) TSP. In both cases the performance of the subject is typically compared to the optimal solution (Fig. 1a), chance (Fig. 1b), and simple heuristic models (Fig. 1c).

### Visual TSP

In psychology, the TSP has been used to assess cognitive functions and complex problem-solving abilities. The task for the subject is to connect an array of dots on a sheet of paper or a computer screen in just one or a few trials. Variants include closed TSPs, in which the tour must start and end at the same node (Fig. 1a–c), and open TSPs, in which the tour must start and end at two different nodes (Fig. 1d).

In such a task, humans can produce paths that approach optimal in problems with up to 100 nodes, generating a solution quickly and with little apparent effort. Human solutions tend to be very good and frequently outstrip the simpler heuristics' solutions despite great variations in the experimental procedures used (e.g., time to complete the task, possibility to erase path)

(MacGregor and Ormerod 1996). Several strategies varying in their levels of complexity (global versus local processing) have been proposed to explain these performances. For example, subjects may simply choose the nearest available unconnected node (nearest neighbor heuristic, Fig. 1c), avoid crossings (crossing-avoidance heuristic), follow borders (convex hull model), or link clusters of nodes (pyramid algorithm). Human performances on visual TSPs do not appear to reflect exclusive use of one of these heuristics, but indicate a probabilistic use of a single or a combination of strategies.

Recently, visual TSPs have been extended to nonhuman animals using smaller arrays of less than ten nodes. For instance, pigeons required to peck nodes on a touchscreen without returning to a previously picked node in order to obtain a food reward perform better than random but significantly worse than the optimal route or a nearest neighbor strategy (Gibson et al. 2007). Hummingbirds also solve simple visual TSPs when collecting sucrose solution on artificial flowers displayed on a vertical board, often choosing the shortest path to visit all flowers once after training (Tello-Ramos et al. 2015).

## Navigational TSP

In ethology, behavioral ecology, and cognitive ecology, the TSP has been used to investigate spatial cognition and navigation behavior. The task for the animal is to find the shortest path to visit multiple baited locations in the lab or in the field. This route optimization problem characterizes the everyday spatial behavior of many central-place foraging animals that exploit food patches from a reference place (nest or shelter). Finding an efficient route between several feeding sites is critical for animals to reduce travel costs and exposure to predators.

The first reported navigational TSP experiment was conducted with chimpanzees that could acquire experience with the spatial distribution of food sites before being tested (Menzel 1973). One experimenter carried a young chimpanzee around a large outdoor enclosure on his back, while a second experimenter hid 18 food items. The chimpanzee was allowed to watch where the food was being hidden and was able to go out and search for the hidden food after being returned to the start location. The routes taken by the experienced chimpanzee were more efficient than the route originally taken by the experimenter, suggesting that while being carried around, the chimpanzee formed a spatial memory of food locations and was able to determine an efficient route between them, following a nearest neighbor strategy. Using a similar procedure, it was found that vervet monkeys have more sophisticated strategies of planning ahead a small number of steps and choosing the path with the shortest length (Cramer and Gallistel 1997).

A second approach to navigational TSP is to test naïve animals that must solve the task as they first discover the problem. In these conditions humans and rats tend to choose routes that are more efficient than expected by chance (Blaser and Ginchansky 2012). Their performance is generally consistent with the use of nearest neighbor strategy, although both produce longer travel distances than would be expected given the sole use of this strategy.

A third approach to navigational TSP is to examine the role of learning and memory in

route optimization by testing animals that can solve the task over multiple trials. In this context, rats (Bures et al. 1992), pigeons (Baron et al. 2015), and bees (Lihoreau et al. 2012) can all develop efficient paths to navigate between multiple locations. For instance, bumblebees allowed to forage for several hours in an array of artificial flowers typically find the shortest possible routes to visit all flowers once and return to the nest. This optimization behavior is reached through trials and errors based on the acquisition of long-term visuospatial memories (Lihoreau et al. 2012). Although the exact strategy used by bees, birds, and rodents to find optimal routes is not known, these results clearly indicate that finding efficient solutions to TSPs does not necessarily require large brains and high computational power.

## Conclusion

The TSP has become an established experimental paradigm in which tasks and memory demands can be easily manipulated to study complex problem-solving by human and nonhuman animals. Interest into the cognitive processes underlying efficient path selection has intensified recently because of the surprising finding that many animals perform well in TSPs. Yet their strategies seem to differ a lot depending on the specificity of the task to solve. Visual and navigational TSPs likely require processing different types of information and different cognitive capacities. For instance, in navigational TSP, goals are generally not marked (which involves increased working memory demands and working with reduced number of nodes) and not visible all at once (which may prevent using global strategies to solve the task). Studies using both approaches in humans and pigeons have started to explore these differences (MacGregor and Ormerod 1996; Gibson et al. 2007; Blaser and Ginchansky 2012). Comparative analyses using standard protocols in a wider range of species with different brain sizes and architectures will help clarify the evolution of fundamental perceptual and cognitive abilities required in these tasks.

## Triadic Awareness

Barbora Kuběňová

Resources, Czech University of Life Sciences,  
Prague, Czech Republic

## Synonyms: Knowledge of Third-Party Relationships

Animals living in stable social groups repeatedly interact with each other. Nonequal distribution of interactions among dyads suggests that animals

differentiate among other group-mates and interact selectively, shaping the number of *agonistic and affiliative relationships*, which are predictive of future interactions. Animals use experience with past agonistic interactions – that define dominance rank relationships – to decide who to fight and who to avoid and to decrease the risk of aggression, injuries, and stress. Tracking of own affiliative interactions helps individuals form and maintain social bonds that decrease stress and bring fitness benefits. The ability to remember past interactions and profit by modifying social behavior based on such memory is an aspect of social cognition, which likely evolved in response to challenges of group living (Seyfarth and Cheney 2015). However, animals living in large stable groups may also profit from more complex cognitive abilities. Evidence accumulated that some animals have certain knowledge about relationships between third parties. They know who outranks whom and who is closely bonded or related with whom and modify own social behavior based on this “triadic awareness.”

There is currently quite convincing evidence from *experimental and behavioral studies* for the triadic awareness in primates (reviewed in Tomasello and Call 1997): Vervet monkeys and chacma baboons demonstrated their understanding of others’ kinship in playback experiments. Individuals were likely to look at the relatives of an individual whose call had been just played. Long-tailed macaques indicated similar knowledge when successfully matching mother-offspring and sibling pairs in a picture-sorting task. Triadic awareness of dominance rank relationships has been inferred from playback experiments using artificial sequences of calls of group members: In chacma baboons calls mimicking interactions that were discordant with the current dominance rank relations between parties elicited stronger reactions of group-members than calls following the hierarchy. Triadic awareness of affiliative relationships was demonstrated by hamadryas and chacma baboons. Males used knowledge of the quality of male-female relationships when deciding whether to challenge a male for access to females.

Although these experiments demonstrate the cognitive capacity for triadic awareness, they

provide only limited information about its use in natural conditions. *Behavioral studies* reveal that primates use the knowledge of third party relationships also in a natural context, during complex social interactions, for example, when redirecting aggression, reconciling after the fight, and forming coalitions. The pattern of reconciliation and redirected aggression in vervet monkeys and several macaque species suggests that these monkeys understand kinship relationships: After the conflict, the aggressor directs reconciliatory behavior at the opponent’s close relatives or avoids affiliative interactions with them in expectation of retaliation, while the victim may redirect aggression towards the opponent’s kin. In the context of coalition formation, which individuals form to access food or mates and rise in social hierarchy, primates use the knowledge of a third party’s kinship, dominance rank, and also affiliative relationships. Triadic awareness helps them predict who will support or intervene against them and select the most suitable ally. For example, juveniles and adult females sooty mangabeys are likely to offer support to the higher ranking of the opponents. When attacked, chimpanzees seem to modify the scream based on rank relationships between opponents and bystanders of a conflict, who might support them. White-faced capuchins preferentially solicit agonistic support from individuals who are more closely bonded to the recruiter than to the opponent, demonstrating their understanding of third party affiliative relationships. Japanese macaques recruit allies who are higher ranking than their opponent and not related to their opponent, suggesting that they can simultaneously use triadic awareness of rank and kinship relationships.

Male bonnet macaques track dominance rank relationships of potential supporters to solicit support from those who outrank their opponent. Unlike relatively stable relations of females in matrilinear societies, dominance rank relationships of males dynamically change depending on their age, actual fighting ability, and coalitionary support they can secure from others. This shows that primates can track even *dynamically changing relationships* (Silk 1999). Different examples of the triadic awareness of such transient

relationships come from Tibetan and Barbary macaques. Males of both species form close relationships with small infants, whom they use in male-infant-male interactions, that is, interactions during which a male carrying an infant approaches another male. Male Tibetan macaques select the infants with the strongest bond with the target male, and male Barbary macaques who carry an infant preferentially approach males who have the strongest bond to the infant they are carrying. Matching males and their favorite infants is likely to increase the efficiency of these interactions that seem so help males bond with others and decrease the risk of aggression from higher-ranking males. Interestingly, bonds between males and infants appear soon after the birth and vanish upon the start of the next mating season. Still, males are able to track those relationships and profit from such knowledge.

The convincing example of the use of triadic awareness by *nonprimates* comes from spotted hyaenas, whose social system is similar to that of many Old World Monkeys. In a fight, hyaenas support dominant from the opponents and attack their enemy's relatives after the conflict (Engh et al. 2005). Other evidence about the use of triadic awareness by nonprimate mammals, however, is somewhat ambiguous. Several studies investigated cognitive abilities in gregarious mammals, such as elephants, bottlenose dolphins, or lions, but the conclusions and their implications remain questionable. For example, experimental studies demonstrate that some marine mammals can recognize relationships between objects in their environment, but it is unclear whether they can also assess other individuals' social relations and use this knowledge. The number of studies suggested the use of triadic awareness by *birds* (e.g., Bond et al. 2004; Pardo et al. 2018). Male great tits and pinyon jays infer their own rank in the hierarchy by observing agonistic interactions between other birds. Ravens modify their calls according to the relationships of their opponents in conflicts. Acorn woodpeckers seem to recognize, whether played calls belong to outsiders from the same or other groups, demonstrating the ability to understand associations between individuals who do not belong to the own social

group. However, it is sometimes questionable whether birds can categorize relationships based on cumulative knowledge, with the delay after the actual interaction.

The explanations for the relative scarcity of evidence for triadic awareness in nonprimates are ambiguous (see Cheney and Seyfarth 2005). It is possible that primates and nonprimates differ in their mental abilities. Nevertheless, several examples of the use of triadic awareness by nonprimates contradict this. The lack of evidence for the use of triadic awareness by nonprimates may be also caused by the small attention nonprimates so far received and difficulties with their research, especially in the wild. Further, the use and manifestation of triadic awareness also depend on the species' social structure. For example, in species that live in a stable group organized into several matrilineal families with linear dominance rank order, such as many Old World Monkeys, individuals may withdraw the information about relationships by monitoring simultaneous interactions of many different individuals. Songbirds like great tits, in contrast, live in communities with no opportunity to get such information, because not all dyads interact.

Species-specific social structure is also likely to affect the *mechanism* of how the triadic awareness is acquired. The straightforward strategy of how one can get to know the relationships between others is by observing and keeping track of their affiliative and agonistic interactions. Nevertheless, the challenge of monitoring interactions of all possible dyads exponentially increases with the increasing group size. Thus, it seems likely that to predict some third-party relationships, individuals also use a system of *transitive interferences* see e.g. Ostner 2018. Such strategy might work well in many primates and also hyenas with the social system organized into matrilineal, and with transitive dominance, and has also been experimentally shown in corvids. An individual who observes individual A be dominant over B and B over C can conclude that A is dominant over C even without witnessing any interaction between A and C. Affiliative interactions between juvenile and female who has an infant likely predict affiliative or kinship

relationships between juvenile and the infant. The transitivity of relationships based on kinship and dominance rank relationships results in certain *ambiguity in findings* (e.g., Perry et al. 2004). Although several studies' results were consistent with the prediction that individuals acted based on triadic awareness, they could not rule out the use of the alternative, more straightforward mechanism. For example, individuals could have also performed based on knowledge of own kin or dominance rank relationship or used a simple rule of thumb, such as "recruit the highest-ranking ally available" or "intervene only if you outrank an opponent."

However, not all relationships are transitive (e.g., Cheney and Seyfarth 2005), suggesting that the mechanism of triadic awareness acquisition also depends on the type of relationships and context. For example, the social bond a male baboon keeps with two different females does not predict either close affiliative relationships between the two females or between the male and the females' juvenile offspring, whose affiliative relationships may reflect earlier bonds of their mothers, rather than the current state. To predict nontransitive third-party affiliative relationships, individuals cannot either use the knowledge of their own relationships or the rule of a thumb. Possibly, they are able to monitor interactions of all or many dyads. However, it is also possible that animals perceive a group as a network of relationships and withdraw the information about third party relationship of dyads from this mental representation even by observing only a subset of their social interactions (Seyfarth and Cheney 2015).

In sum, there is quite compelling evidence from observational and experimental studies that nonhuman primates possess the capacity to monitor others' social relationships and use it for their own benefit. Overcoming ambiguity of the results, revealing an exact mechanism of triadic awareness acquisition, and finding new contexts where individuals use triadic awareness might represent appropriate future research directions. The examples of the use of triadic awareness by nonprimates support the *social intelligence hypothesis* that predicts that the ability to

recognize "third-party" relationships is advantageous whenever individuals live in large social groups (Humphrey 1976). Further focus on the use of triadic awareness by nonprimates will help us comprehend the role of group living in the evolution of cognition in social animals, including humans.

interaction, shared intentionality, joint action, and finally, joint attention (Tomasello et al. 2007; Sebanz and Knoblich 2009). Joint attention is considered as the prerequisite of cooperation (Tomasello et al. 2007) and has been investigated in great detail (e.g., Kleinke 1986; Grossmann 2017; Leavens and Clark 2017 this volume). As a synonymous phenomenon, Emery (2000) described that “shared attention” is a combination of joint attention and mutual attention where the focus of two individuals’ attention is on the object of joint focus and also each other (i.e., I know that you are looking at X, and you know that I am looking at X as well).

## Triadic Gaze

Sanae Okamoto-Barth  
Faculty of Psychology and Neuroscience,  
Maastricht University, Maastricht,  
The Netherlands

### Definition of Triadic Gaze

Triadic gaze requires two individuals (a looking individual and a perceiver) and a third party (an object, event, or a person) as the focus of the attention of the individuals. It involves a relatively more complex information processing mechanism than a dyadic gaze that requires perceivers to identify whether a looking individual’s eyes are directed toward them. To achieve triadic eye gaze, the perceiver must recognize the line of site of the looking individual’s eyes and trace along two invisible lines of the site to their convergent point, that is, the third party of the triad (e.g., an object; Lee et al. 1998). Although triadic eye gaze can also be used to regulate one-to-one social interaction, another major and unique function of triadic eye gaze is that it can be used to reveal an individual’s focus of attention and internal states (desire, goal, etc.; Lee et al. 1998). In the literatures of human developmental studies, triadic gaze that mutually coordinates attention of two individuals is considered as a hallmark of social learning, communication, social

### Early Form of Triadic Gaze Interaction

Between 4 and 6 months of age, human infants become interested in the visual and tactile properties of objects. Consequently, the proportion of time that infants spend with mutual gaze in face-to-face interactions is reduced quite considerably by 6 months (Kaye and Fogel 1980) because other objects are now detracting attention away from faces. Mothers typically recognize this change and introduce objects such as toys into their interactions with their infants. By 6 months infants have become interested in things, but at first they do not share this interest with others. Initially, the infants’ role in such object-centered interactions is confined to manipulating the object. Gradually, over the next few months, the interactions become reciprocal. Rather than simply concentrating on the object, infants take their turn and then look up at their mother’s face as they anticipate the mother’s turn. Infants have now entered the period of real means of joint attention (see Leavens and Clark 2017 this volume for Joint Attention) or joint attentional engagement (Carpenter and Call 2013) and have reached a new cognitive milestone. That is, from now on, interactions are primarily triadic (Bakeman and Adamson 1984) because they involve three components – infant, adult, and object – where previously they were dyadic (infant and adult only). Triadic interactions often retain the structure of dyadic interactions in that they involve mutually contingent patterns of

actions produced by both partners (Dunham and Dunham 1995; Striano and Rochat 1999).

Recently, Jording and co-authors (2018) classified taxonomy for gaze-based communication in triadic interaction as a “social gaze space.” Accordingly, “initiating joint attention (IJA)” and “responding joint attention (RJA)” are the categorical states that have significant roles in a coordination of triadic gaze interaction (see also Leavens and Clark 2017 for this volume). RJA can be defined as a perceiver notices that a looking individual initiates and leads the interaction and shifts gaze toward an object. It is considered to facilitate social learning, social competence, and mentalizing (Morales et al. 1998; Mundy and Newell 2007). That is, RJA reflects that the perceiver understands that the perception and actions of the looking individual are goal directed or have communicative intent (Tomasello et al. 2005). Contrarily, IJA requires more elaborate processing and insight as it contains the dual function of social gaze, which is not only for perceiving but also for informing others about the individual’s focus of attention and sharing of attention as an intention for mutual interaction (Grossmann 2017; Gobel et al. 2015; Tomasello et al. 2005).

### Chimpanzees, Other Apes, and Triadic Gaze Interaction

A number of studies demonstrated that chimpanzees and other apes (bonobos, gorillas, and orangutans) are able to follow gaze of others (Povinelli and Eddy 1996; Tomasello et al. 1998; Tomasello et al. 2005; Okamoto-Barth et al. 2007; Bräuer et al. 2005; Call and Tomasello 2008) and are also motivated to attend the same thing that others are attending to. Chimpanzees are also able and motivated to direct other’s attention to things they themselves are looking at (e.g., Menzel 1999; Leavens et al. 2004; Call and Tomasello 2007; Lyn et al. 2011). Although there have been some debates whether apes engage in initiating to share attention and interest with others during joint attentional engagement or by using declarative gestures such as showing or declarative pointing as human infants do (e.g., Gómez et al. 1993;

Tomasello et al. 2005; Tomonaga et al. 2004), these incidences (yet less frequent) have occasionally been observed in the wild and laboratory settings (see also Leavens and Clarks for review, 2017 this volume).

### Conclusion

While human infants respond to joint attention from 6 months of age, they don’t initiate joint attention before the second year of life (Mundy and Newell 2007). Chimpanzees and other apes demonstrate IJA not at the same frequency as RJA (e.g., Tomasello et al. 2005; Leavens et al. 2004; Lyn et al. 2011). A recent neuroimaging study (Oberwille et al. 2016) revealed a developmental difference in brain systems for RJA and IJA from childhood to adolescence in humans. While RJA recruits the visual, attention, and social processing brain regions, IJA specifically activates areas that are involved in social cognition, decision-making, emotions, and reward processing, suggesting the rewarding and more complex processing nature of IJA. Interestingly, IJA is more impaired and emerges much later than RJA in autism (Mundy 2003). These empirical findings together suggest separate underlying cognitive systems of RJA and IJA in triadic gaze interaction (Mundy and Newell 2007).

## Trisomy

Abhimanyu Kumar Jha

Department of Biotechnology, Faculty of Life Sciences, Institute of Applied Medicines and Research, Ghaziabad, UP, India

Department of Biotechnology, IMS Engineering College, Ghaziabad, UP, India

Department of Biotechnology, School of Engineering and Technology, Sharda University, Greater Noida, India

## Synonyms

[Chromosomal aberration](#); [Chromosomal abnormality](#); [Chromosomal anomaly](#)

## Definition

The term trisomy refers to the presence of three copies of a chromosome, rather than the usual pair of chromosomes. Normally there are copies of a chromosome in every individual, one from each parent. If an infant is born with three # 18 chromosomes, the infant would be said to have “trisomy 18.” Trisomy 18 is also known as Edward syndrome. Other examples of trisomy include trisomy 21 and trisomy 13. A **trisomy** is a type of chromosomal disorder or aneuploidy (abnormal number of chromosomes) in which three copies of a particular chromosome are present, instead of the normal two (Rieger et al. [1968](#)).

## Introduction

Most of the sexually reproducing organisms have pairs of chromosomes in each cell. One chromosome is inherited from each parent. Through meiosis, gametes (eggs or sperm) are made that are haploid or that have only one set of chromosomes. The number of chromosomes is different for different species. Humans have a diploid set ( $2n$ ), i.e., 46 chromosomes. However, gametes have only a haploid set ( $n$ ), i.e., 23 chromosomes.

The main cause of trisomy is nondisjunction of chromosomes. The number of chromosomes in the cell where trisomy occurs is represented by  $2n+1$  if trisomy is shown by one chromosome whereas it is represented by  $2n+1+1$  if it shows double trisomy and so on (Hassold et al. [1995](#)).

## Types of Trisomies and Down Syndrome as Trisomy

Trisomies may be characterized as autosomal trisomies (trisomies of the non-sex chromosomes) and sex-chromosome trisomies. Viable trisomies are observed in the case of only a few human chromosomes. The most common human trisomy is observed in chromosome 21 and is known as Down syndrome (DS), named after John Langdon

Down (O'Connor 2008) who first described the condition in 1866 (Antonarakis et al. 2004). Jerome Lejeune associated DS with trisomy 21 in 1959. His discovery is a landmark in the field (Antonarakis et al. 2004). Joe HinTijo and Albert Levan had discovered that the human chromosome number is 46, and chromosome-staining techniques were still being developed at that time.

DS is routinely identified in karyotypes as ideogram or by using fluorescent probes for chromosome 21 through fluorescence *in situ* hybridization (FISH) (Antonarakis et al. 2004). Down syndrome affects about 1 in every 750 births (Antonarakis et al. 2004). Individuals with DS show cognitive impairment, along with a more variable range of other symptoms, but patients normally live to adulthood (Patterson and Costa 2005), whereas trisomies of other autosomes appear to have more severe effects, because they are rarely observed in live births. Indeed, the only other autosomal trisomies that have been detected in any appreciable numbers among newborns involve chromosomes 13 and 18, but affected babies rarely survive beyond the first few months of life.

It has been observed that human beings are much more able to tolerate extra sex chromosomes than extra autosomes. Therefore, after DS, the most common human aneuploidy is the condition known as Klinefelter's syndrome (Jacobs and Strong 1959).

## Detrimental Aftereffects of Extra Chromosomes

Klinefelter's males have a total chromosomal complement of 47, which includes two X chromosomes and one Y chromosome. These sterile males are designated as 47, XXY individuals. Compared to autosomal trisomies, these sex chromosome trisomies are less dangerous. Affected individuals generally show reduced sexual development and fertility, but they often have normal life spans, and many of their symptoms can be treated by hormone supplementation. The ability of humans to tolerate supernumerary sex chromosomes is

higher as compared to supernumerary autosomes, as individuals can survive with as many as four sex chromosomes. This tolerance most likely relates to both X inactivation and to the lesser number of genes on the Y chromosome (O'Connor 2008). The genes present on Y chromosome are called holandric genes and are much fewer in number. If an X chromosome is present in two copies, one of the copies is inactivated.

Trisomies can occur with any chromosome, but most of the time, it results in miscarriage, rather than live birth. For example, Trisomy 16 is one of the most common trisomies in human pregnancies, occurring in more than 1% of pregnancies; only those pregnancies in which some normal cells occur in addition to the trisomic cells survive (O'Connor 2008). This condition, however, usually results in spontaneous miscarriage in the first trimester.

Trisomy 13, also called Patau syndrome, is a chromosomal condition associated with severe mental retardation and physical abnormalities. In rare cases, a fetus with Trisomy 13 can survive but they have been observed with heart defects, brain or spinal cord abnormalities, microphthalmia, a cleft lip with or without an opening in the roof of the mouth (a cleft palate), etc., in addition to impaired intelligence. Only 5–10% of children with this condition are able to survive past their first year.

## Conclusion

In sum, the common types of *autosomal* trisomy that survive as live births are:

- Trisomy 21 (*Down syndrome*)
- Trisomy 18 (*Edwards syndrome*)
- Trisomy 13 (*Patau syndrome*)

The trisomies are associated with the presence of an extra chromosome in addition to the existing ones. In most of the cases, the individual is not able to survive, but in some of the cases in which the individual is able to survive, severe symptoms lead to distinct abnormalities.

## Troop

Sarah M. Huskisson  
Lester E. Fisher Center for the Study and  
Conservation of Apes, Lincoln Park Zoo,  
Chicago, IL, USA

## Definition

A troop refers to a group of animals, typically kangaroos, wallabies, apes, or monkeys.

## Introduction

Groups of primates, kangaroos, and wallabies are called “troops,” although kangaroo and wallaby groups can also be called a “mob,” apes a “shrewdness” or “community,” and monkeys a

“barrel.” Troop life across species somewhat mirror each other, in that troops are highly social with some form of dominance hierarchy. Troops may be synonymous with family groups but may also be comprised of unrelated individuals.

## Kangaroos and Wallabies

There are four distinct species of the Australian marsupial “kangaroos”: red (*Macropus rufus*), antilopine (*M. antilopinus*), eastern grey (*M. giganteus*), and western grey (*M. fuliginosus*). Kangaroos are herbivorous and can be found in grasslands and open forests across Australia and Tasmania. Kangaroo troops usually consist of multiple adult females, offspring, and at least one dominant male with variations occurring across geographic regions. For instance, eastern grey kangaroo troops typically contain an equal number of males and females with a designated dominant male (Dawson 1998). Troops can range anywhere from two to four individuals, such a mother-offspring pair or small polygynous group to ten or more. In areas of dense forage material, kangaroos can congregate in numbers exceeding a thousand, potentially as a result of intertroop interactions. It has been noted that groups are larger in eastern Australian species rather than western due to environmental conditions (Dawson 1998).

As troops grow, group cohesion is important, which is why kangaroos can often be found sniffing or touching noses to promote unity (Dawson 1998). Ritualized boxing establishes dominance among troop males. In each group, a dominant male controls the troop and has equal reproductive access to sexually mature females. However, troops that contain multiple males may witness bouts of fighting for breeding rights with cycling females (Dawson 1998). In either case, females will signal when they are in estrus, encouraging consort pairing with another male. Consort pair bonds are temporary and can persist for several days, which can alert other males to the breeding opportunity and again result in fighting. However, both sexes within a troop may transfer to other troops. Eastern grey kangaroo dispersal is perhaps the most well-understood: females often

remain close to female relatives throughout life, whereas males disperse more readily, albeit not frequently (Coghlan et al. 2017). Information for other species is inconsistent.

Wallabies belong to the same taxonomic family as kangaroos (Macropodidae) and are distinguished based on their smaller size. There are approximately 44 species (genera *Macropus*, *Petrogale*, and *Lagostrophus*) found in rugged and remote terrain across Australia, New Zealand, and New Guinea.

Some species, like the red-necked wallaby (*Macropus rufogriseus*), are mostly solitary and any existing troops are often small and unstable. More gregarious species of wallabies, like agile wallabies (*M. agilis*), adhere to the troop structure exhibited by kangaroos. Regardless of species' social structure, consort pairs are temporary. When troops meet, there is often combat between males. Females tolerate the presence of other females within and between troops, although they may displace one another through agonistic interactions (Johnson 1989).

## Apes

Great apes are the world's largest primates and are found only in Africa and Asia. Orangutans (*Pongo* sp.) are found on the islands of Sumatra and Borneo. Gorillas (*Gorilla* sp.) and chimpanzees (*Pan troglodytes*) live in sub-Saharan Africa and bonobos (*Pan paniscus*) live exclusively in the Democratic Republic of Congo.

Apes are gregarious animals, with the exception of the orangutan (*Pongo* sp.), which maintains a mostly solitary lifestyle. Members of *Pan* and *Gorilla* live in dynamic social groups (which may have led to the cultivation of their impressive intellectual abilities), ranging from around nine individuals (gorillas, *Gorilla* sp.) to over a hundred individuals (chimpanzees and bonobos, *Pan* sp.). Particularly large ape troops are usually subject to fission-fusion dynamics. The troop may fuse, for example, to sleep and may split apart into smaller foraging groups during the day. This dynamic association ultimately maintains large troops, as group members regularly return to the

main "parent group" to reassume their role or rank in their society.

In gorillas, group composition varies somewhat based on species. Mountain gorilla troops usually consist of a single male, multiple females, and offspring, whereas lowland gorilla troops more often have multiple males. Additionally, multi-male "bachelor" troops exist for both species, although a much rarer occurrence for mountain gorillas. Both males and females emigrate from their natal groups at around 8–12 years of age, and females often transfer many more times to secondary troops. In mixed-sex, multi-male groups, the silverback male is the highest-ranking individual in his troop, as he makes group decisions and ameliorates conflict among members. Females keep a largely egalitarian society, although older females may obtain a higher status than younger females due to age and experience (Harcourt and Stewart 2007). Relationships between females are reinforced by maintaining close proximity and grooming.

Chimpanzee troops typically include several males, females, and offspring. Males often stay in natal groups for life while females transfer around 9–14 years of age. As a result, most females in troops are unrelated. In chimpanzee troops, both males and females have strong intrasexual dominance hierarchies. The highest-ranking male controls troop activities and enforces order during disputes (Mitani et al. 2012). Moreover, the alpha male typically enjoys expanded mating opportunities within the troop compared to lower-ranking males. Females may inherit the ranking of their mother or fight to achieve elevated status. Female dominance is established by age, and dominant females may obtain increased resource access. This can increase reproductive output, offspring survival, and maturity rates. In both sexes, dominance is bolstered by ally recruitment within the community (Mitani et al. 2012). This becomes especially valuable in intertroop conflict, typically among males, over territory or other resources.

Bonobo groups are composed of multiple males and females, although composition varies. Females are generally unrelated due to dispersal at puberty, while males maintain relatedness due to infrequent group transfer. Interestingly, females

have been observed to exchange more affiliative behavior than males despite a lack of shared ancestry (Mitani et al. 2012). Contrary to gorilla and chimpanzee societies, a distinctive feature of bonobo troops is that females enjoy a higher social status than most males (White 1996). An exception is when a male inherits his standing from his mother and consequently ranks higher than a lower-ranking female. Despite this, bonobo status does not play a significant role in day-to-day life (White 1996). Bonobos also utilize sociosexual behavior to promote troop cohesion, perhaps more so than other apes. Consequently, physical confrontation is kept to a minimum within and between bonobo troops compared to other ape groups.

## Monkeys

Monkeys are among the most biodiverse mammal groups, with hundreds of species living in an array of niches worldwide. Monkeys are broadly categorized as New World (the Americas) and Old World (Africa, Asia, and Europe). Neotropical primates belong to five families: Callitrichidae (tamarins and marmosets), Cebidae (capuchins, squirrel monkeys), Aotidae (night monkeys), Pitheciidae (titis, sakis, uakaris), and Atelidae (howler, spider, woolly monkeys). Troop sizes vary among species, and can range from large multi-male, multi-female groups, as in saki (*Pithecia* sp.) troops, to pair-bonded individuals, as in golden lion tamarins (*Leontopithecus rosalia*) (Dietz and Baker 1993). Many other species of neotropical primates are socially monogamous, including other tamarins and marmosets, titi monkeys, and night monkeys. In these pairings, both individuals, to varying degrees, raise offspring. In night monkeys, males assume most of the parenting responsibility, and it is predicted this increases offspring survival and reduces the female's metabolic costs.

Multi-male, multi-female troops typically have more females than males, and there is usually a dominant male in the main group, and potentially in subgroups, if fission-fusion dynamics are involved in the species' society (Mitani et al.

2012). However, some polygynist troops, like those of squirrel monkeys (*Saimiri* sp.), allow females to obtain comparable rank to males (Mitani et al. 2012). In species with large troop sizes, there is dispersal in both sexes, although some species, like the uakari (*Cacajao* sp.) and muriqui (*Brachyteles* sp.), appear to be biased toward female transfer from the natal group (Mitani et al. 2012).

Old World monkeys include two subfamilies: Cercopithecinae (e.g., patas monkeys, mandrills) and Colobinae (e.g., colobus, langurs). Troop sizes can range from a few individuals, like in green monkeys (*Chlorocebus aethiops*), to up to around 200, such as in Guinea baboons (*Papio papio*). Virtually all species live in multi-male, multi-female groups. Groups are often matrilineal, given that daughters usually stay with their mothers (e.g., *Macaca* sp.). Males leave natal troops upon reaching adolescence. Separate dominance hierarchies exist for each sex, and rank is often correlated with tenure among males (Mitani et al. 2012). In some cases, mating behavior differs greatly in monkey troops, as it depends on social structure. Some troops, like those of savanna baboons (*P. cynocephalus*), permit all males to mate with any female, whereas in others (e.g., *M. fuscata*), mating privilege follows rank (Barton et al. 1996; Mitani et al. 2012).

As with apes, large monkey troops may experience fission-fusion dynamics. In some troops, as in Japanese macaques (*M. fuscata*), subgroups can outrank other subgroups. In baboon troops, subgroups are called harems, in which a male dominates over a group of females (Barton et al. 1996). Males may fight to gain control of another harem and may take infants as hostages during the course of a conflict. As an alternative to physical confrontation, baboons have the ability to determine dominance rank from the exchange of vocalizations within or between troops. Troops of any size are often maintained through grooming, which strengthens bonds between kin and nonkin.

In both New World and Old World monkey groups, the quality of intertroop interactions may be determined by the resources and opportunities held by the troops involved. For example, larger groups with increased potential for energy gain

may defend their food, territory, and/or mates more strongly than smaller groups (Scarry 2017). One specific study of vervet monkeys (*Chlorocebus pygerythrus*) observed that the nature of intertroop encounters could be predicted by previous male transfers from an outside group. When males attempted to transfer to a secondary group, the members of that secondary group exhibited more aggression, possibly in defense of their resources (Cheney 1981).

## Causes and Benefits of Troop Life

Inherent in troop social structure is the potential for increased competition, agonism, and aggression, which may cause increased energy expenditure and chronic stress in troop members, particularly those of lower rank (as applicable). Furthermore, gregarious species expose themselves to increased disease risk, since frequent interaction and close proximity facilitate the pathogen transmission. Despite this, troop structure plays an important role in animals' lives and their greater benefit.

One major benefit of troop life is protection from predation. With more members, it is easier to spot external threats and act accordingly to prevent loss of life. While the cost to this may be a reduction in feeding sites, for example, the benefit of defense surpasses it. In such a situation, altruism may also be witnessed. If a troop member alerts the other members of a potential threat (e.g., a vervet monkey alarm calling upon seeing an eagle overhead), the caller puts itself in danger for the troop's benefit (Cheney and Seyfarth 1981). Additionally, altruism is a more common occurrence when genetic relatives will be benefited by the altruist's actions. Altruistic behavior may be one of the ultimate causes in the maintenance of troops, as it helps an altruist ensure that its own relatives and future offspring with an unrelated individual are successful.

Another benefit to troop living is increased communication among members. Troop members notify others about the location of food or threats, for instance, providing pertinent information that can shape animals' actions. It has been suggested

that communication among troop members may benefit each individual's health in the long run, particularly where food is concerned, as information about high-quality food is frequently transmitted through groups.

Troops also provide plentiful learning opportunities throughout an animal's life. The social group provides the first safe place for young animals to develop both physically and mentally. Playing with other juveniles allows for the development of motor skills as well as a platform to learn the right and wrong ways of going through day-to-day life. Troop structure may inherently give rise to sophisticated intelligence, such as among primates, as troop members spend so much time in close proximity to others from whom they can learn.

## Tropical

### ► Tropics

---

## Tropics

Yashpal Bhardwaj  
Laboratory of Molecular Ecology, Department of Botany, Institute of Science, Banaras Hindu University, Varanasi, India

## Synonyms

Equatorial; Tropical

## Definition

The geographical regions surrounding the equator and between the latitudes lines of Tropic of Cancer in northern hemisphere (23° 27' N) and Tropic of Capricorn in southern hemisphere (23° 27'S) are referred as tropics or tropical zone or torrid zone.

## Introduction

The tropics are regions of the Earth that are in the middle of the globe and between the latitude lines

of the Tropic of Cancer and the Tropic of Capricorn (Fig. 1). It comprises 40% of the total Earth's surface area which include the equator and parts of North America, South America, Africa, Asia, and Australia. Tropical regions are warmer than any other places on Earth with all 12 months of the year having temperature above 18° C. The warmer climate of tropics can be explained by Earth's spherical shape due to which it receives highest solar radiation around equatorial regions. The solar radiation reduces with increasing latitude resulting cooler climate near the poles. Relatively constant temperature and high humidity support luxuriant vegetation and a great biodiversity of flora, fauna, and microbial organisms in tropics. Tropical ecosystems exist in a large diversity of habitat types such as rainforests, dry forests, savannas, deserts, and many more. These are characterized by both high richness of species in many taxa and complex biotic interactions among component species. Most tropical plants are animal pollinated, are fed on by a wide variety of animals, and depend on animals for dispersal of their seeds. Approximately, 1.5 billion people are estimated to directly rely on tropical forests for food, timber, medicines, and other important ecosystem functions and services (Lewis et al. 2015). These ever-growing human demand for resources, however, is putting huge pressures on biodiversity which threatens the continued provision of ecosystem services and further threatens biodiversity and our own species' future security, health, and well-being. For sustainable use of natural resources of tropics and to prevent species from extinction in the near future, actions to conserve their remaining habitat in these areas are urgently required (Bax et al. 2019).

## Climate of Tropics

The climate of the tropics is different from other climatic zones and largely driven by the solar energy. The solar radiations are more directly on the tropics than on higher latitude (like poles) which makes the tropics to receive more energy and become warmer than the pole. Differential heating of Earth's surface generates circulations

**Tropics, Fig. 1** World map indicating the tropical zone

of air and water masses, which allow heat exchanges between the Earth's zones. Tropical air moves away from the equator and toward the poles. As it travels, it cools, becomes denser and eventually descends around 30° north or south latitude. This dry air mass, having lost its moisture in the tropics in form of precipitation, absorbs moisture from the ground, creating arid conditions at these latitudes. The major deserts of the world like Sahara Desert, Arabian Desert, Thar Desert, Kalahari Desert, and Gibson Desert are situated at these latitudes on the either side of the equator. Some of the air is drawn back toward the equator, and some is drawn toward the pole as part of a new air mass. At latitudes around 60° north and south, the air again rises, cools, and releases precipitation (though less than in the tropics). This cycle operates and repeats and results into warm and humid condition in tropics. Some of the cold, dry rising air then flows to the poles, where it absorbs moisture creating the cold climates of the polar regions. The Earth's rotation also influences the atmospheric circulation more strongly at high latitudes than low. The above factors result in more clouds and rain storms in the tropics spontaneously compared to those at higher latitudes,

where they are more tightly controlled by larger-scale forces in the atmosphere. Because of these differences, clouds and rain are more difficult to forecast in the tropics than at higher latitudes. On contrary, the temperature is easily forecasted in the tropics, because it remains stable.

### Biodiversity of Tropics

The tropical forests contain more than half of the species on Earth. In general it is argued that most of the main groups of large organisms on Earth, like plants and animals, and the number of species increase markedly toward the equator. The tropics represent an exceptionally high biodiversity of plants, birds, insects (especially ants, beetles, butterflies, and termites), amphibians, mammals, and other organism groups. They also contain particularly high biodiversity and especially high numbers of endemic species. This huge biodiversity is supported by various tropical ecosystems that exist in a large diversity of habitat types such as rainforests, dry forests, savannas, deserts, and others. In fact, tropical habitats represent an important component in all Earth's life diversity,

because great part of the 34 biodiversity hotspots (areas of high numbers of endemic species) are tropical ecosystems (Myers 1988).

## Threats to Biodiversity of Tropics

Tropical ecosystems have always attracted the attention of scientists due to their impressive biodiversity, but recent trends have made the study of tropical biodiversity particularly important (Gómez-Pompa 2004). Threats to tropical terrestrial biodiversity result from the synergistic effects of several anthropogenic disturbances that can be grouped into at least three main categories which include deforestation, degradation of ecosystem, and landscape effect. Thus, contemporary loss of biodiversity will likely lead to subsequent changes in ecosystem properties and stability. Several studies have been conducted in the lab, grassland, forest, marine, and freshwater ecosystems and clearly concluded that ecosystem functioning depends on species richness, species composition, and functional group richness and can also depend on species evenness and genetic diversity as well. Therefore, we urgently need to assess tropical diversity changes in landscapes disturbed by humans in the Anthropocene, a new geological epoch in which humans have significantly altered biodiversity, with consequences for planetary functioning (Corlett 2015).

## Conclusions

Tropics cover the large area of the Earth's surface and are instrumental to sustaining the all life forms on the Earth. For instance, the Amazonian rainforests of Brazil are considered to be the "lungs of the planet" as it absorbs CO<sub>2</sub> and therefore helps to protect the Earth against the greenhouse effect. Currently, the international agencies working in the environmental issues must consider the tropics on the top priorities to protect and conserve its immense natural resources and engage people in biodiversity and other environmental issues.

## Turing Test

Kevin Warwick  
Coventry University, Coventry, UK

## Synonyms

Discourse; Imitation game; Hidden humans; Lying; Machine thinking; Misidentification

## Introduction

The ability of humans, and indeed other animals, to think plays a critical role in their cognition, understanding, and communication. But what exactly does it mean for an entity to think? Is it possible to measure thinking in some way? Can a machine be made to think in the same sort of way as a human?

Turing's imitation game, commonly known as the Turing test, was originally posed by Alan Turing as a "closely related" alternative to the question of whether or not a machine could be said to think (Turing 1950), something which could be "expressed in relatively unambiguous words." With regard to the question "Can machines think?" Turing actually felt this "to be too meaningless to deserve discussion." An important reason for this was the problem of agreeing on "definitions of the meaning of the terms 'machine' and 'think'." With regard to machines, Turing did though exclude biological systems such as cellular growths (Warwick et al. 2010) and even "men born in the usual manner," stating "we only permit digital computers."

Since that paper appeared, a lot of discussion has focused on the concept of machine thinking and whether it can be humanlike at times or even whether it will ever be possible to copy human thinking in all its aspects (Dennett 1998; Dreyfus and Dreyfus 2009; Minsky 1982; Shah 2010). Turing suggested, "May not machines carry out something which ought to be described as thinking but which is very different from what a man does?" (Turing 1950). As a result, some

researchers in the field regard the test as laying the foundations for what is now known as artificial intelligence (AI), even considering it to be AI's "empirical goal" (Harnad 1992).

The game involves human interrogators attempting to ascertain the nature of hidden (human and computer) entities with whom/which they are communicating. As indicated by Turing in Turing (1950), each discourse lasts for a period of 5 minutes only, and at the end of that time, the interrogator is charged with making the "right identification" by clearly identifying the nature of their hidden discourse partners by declaring which is the human and which is the machine (Warwick and Shah 2016a).

In considering the game in further depth, one is faced with numerous intriguing questions regarding human and machine communication and behavior. When comparing a human's ability to communicate, one immediately has to consider the fallibility, biases, and preconceptions of that person. One also must take into account important aspects of human nature such as lying, misunderstanding, lack of knowledge and humor, and never mind stupidity.

Over the last few years, a number of practical Turing test sessions have been organized involving some of the best conversation machines in the world; these followed as closely as possible with the test description as given by Turing himself in his seminal paper of 1950 (Turing 1950). One set of such experiments was held at Bletchley Park, England, in 2012. Another was held at the Royal Society, London, in 2014. The latter involved the largest number of tests ever staged in any single event.

In this article, the author reports on actual transcripts from these tests as a basis to investigate just what it takes to fool a human interrogator and how examples of the use of humor and lying have affected decisions. In addition, a look is taken at a series of cases in which human communicators have been clearly categorized by interrogators as definitely being machines and others in which machine communicators have been clearly categorized by interrogators as being human.

The transcripts between judges and hidden entities presented here are taken from tests in

which a human judge carried out a 5-minute-long conversation with two hidden entities in parallel. One of the entities was a human and the other was a machine. It was very much up to the judge as to the nature of the conversation, and it was their decision as to how much time they spent conversing with each of the entities during the 5-minute period.

In a particular session, a judge conducted five separate tests. In their first test, they witnessed a hidden human pitted against a hidden machine. Of course the judge would not know which was which; they would simply be aware of two hidden entities and have to make their own decision on the nature of the entities, although they had been informed *a priori* that one entity was human and one was a machine. The second test conducted by the judge then involved a different human pitted against a different machine, although again they would not be aware of each entity's nature. And so it would go on until the judge had conducted all their five tests in that session. At the end of each test, they were asked to state for each entity if they thought that it was a human or a machine or if they were unsure.

In the tests, the hidden humans were asked merely to be themselves, although they were requested not to give away their specific identity or personal information. They were not given any incentive to behave in a particular way and were given no payment at all. Of course this did not prevent any human from giving false information, which is something that humans do frequently. The tests were "unrestricted conversations," which meant the judge could ask anything or introduce any topic within the boundaries of courtesy (the judges had been informed however that there may be children among the hidden human entities).

## Turing Test Details

The conversations presented here were realized as a result of five-minute-long tests of human judge-hidden entity interaction, to conform to Turing's original wording in computing machinery and intelligence (Turing 1950).

What this paper does is to present a number of transcripts taken from practical Turing tests, which were held under strict conditions with many external viewers first at Bletchley Park, England, on June 23, 2012. The date marked the 100th anniversary of Turing's birth and the venue was that at which, during the Second World War, Turing led a team of code breakers to crack the German Enigma machine cipher. The second set of tests was held on June 6–7, 2014 at the Royal Society, London, of which Alan Turing was a fellow. Five different machines took part in both sets of tests along with 30 different judges and 30 hidden humans against which the machines were compared in terms of their conversational ability. Although the machines were common to the two experiments, the judges and hidden humans were a different collection of people.

In this article, one is certainly interested in how good or bad the machines are; indeed, it is interesting to look at how good they can be. But one is also interested in the operational performance of the judges and specifically how they interacted in conversation with hidden entities. Hidden humans are, by definition, human, but (Shah and Warwick 2010; Warwick and Shah 2015a) can themselves be misidentified on occasion? An attribution of *humanness* by a human interrogator to a hidden interlocutor in a practical Turing test is dependent on the judge's own values of what constitutes humanlike conversational behavior. Good performance of machines is largely discussed elsewhere (Warwick and Shah 2014a), although a couple of examples are given here in a separate section for comparative purposes.

A look is taken into Turing's statement that the test/game can be considered as a replacement for the question "Can machines think?" (Turing 1950). While it is acknowledged that the results in each case depend on the performance of the judge, far from the conditions of the game saying nothing about the judge, this aspect is seen here to be very much a critical part of the test itself. Importantly, in the test, machines are pitched against (hidden) humans under the critical analysis of other (interrogator) humans. These are all very important aspects of what the test is about and are certainly not points of fallibility of the

game as has been suggested by Hayes and Ford (1995).

In the sections that follow, different examples of practical tests are given, and an attempt is made to cover a wide range of problem areas as they exist at present, which the test highlights. In each case, discussion on the transcript is carried out within that section, where it is pertinent. However, a number of universal comments are also made in the conclusions section toward the end of the article.

The transcripts considered in this paper appear exactly as they occurred. They have not been altered in any way in terms of the sequence or wording or corrected spelling. Once an utterance was outputted, it was not possible for the judge or hidden entity to alter it in any way. The timings shown are accurate, actual timings on the days (UK time) involved. Any spelling mistakes or other grammatical errors were exactly as they happened. They are not due to editorial errors. In the transcripts, the interviewer/judge is always denoted as “judge,” whereas the hidden interlocutors, machine or human, are denoted as “entity.”

## Lying

Lying is a part of human nature and therefore has a role to play when it comes to the Turing test. The machine’s goal is deception attempting to mislead the interrogator that it is a human. Meanwhile, hidden humans are requested not to give away exactly who they are through revealing personal details, as this might aid the interrogator, but apart from that they can simply be themselves. Lying can take on many different forms from a white lie to an unintentional lie to a complete untruth. What one is interested in is the effect of a lie on the decision taken by the interrogator. Please see Warwick and Shah (2016b) for an in-depth analysis of these and many more transcripts.

Transcript 1:

[12:43:23] Judge: Why hello there!

[12:43:41] Entity: Why hello to you too!

[12:44:51] Judge: How are you feeling on this fine day?

[12:45:12] Entity: To be quite honest a little rejected, I thought you were never going to reply :(

[12:45:42] Judge: Oh, I’m very sorry, it will not happen again.

[12:45:49] Entity: It just did!

[12:46:46] Judge: Oh, I lied then.

[12:47:12] Entity: That’s a great shame indeed.

[12:47:34] Judge: It is. Are you following the Euro 2012’s at the moment?

[12:47:55] Entity: Yeah quite closely actually. I am Cristiano Ronaldo.

The main issue with this transcript occurs in the last couple of lines. The Euro 2012 refers to the European nations’ football competition which was being held at exactly the same time as the Turing event. Many people were watching the matches on television. Cristiano Ronaldo is a Portuguese footballer. The last line reply, merely agreeing with the judge’s specific question, appears to have been sufficient to correctly categorize the entity, in the judge’s opinion, as being a human. This was probably sealed by the “humorous” comment with the entity claiming to be Cristiano Ronaldo.

Interestingly, the specific knowledge tester about Euro 2012 was dealt with by the entity agreeing with the comment. However, the human entity openly lied about being Cristiano Ronaldo who was himself not taking part in the experiments. The interrogator may well have seen the humorous lie as supporting evidence of the entity being human. In this case, the white lie had no negative effect.

## Misidentification

In this section, two cases are included in which a misidentification has occurred. The second of these could be regarded as a good outcome in that it involves a machine being incorrectly classified as a human. The first case however involves a human misidentification and was reported on in greater depth in Warwick et al. (2013).

Transcript 2:

[10:58:45] Judge: Hi there

[10:58:55] Entity: Hi, how are you?  
 [10:59:02] Judge: I'm good.  
 [10:59:21] Entity: what, that's your name, like in the Good Life?  
 [10:59:36] Judge: What do you mean by 'Good Life'?  
 [10:59:47] Entity: Tom and Barbara  
 [11:00:02] Judge: What's that?  
 [11:00:31] Entity: A couple who left the rat race  
 [11:01:03] Judge: Oh. Is that your names? Wonderful to have left the rat race. How long ago was that?  
 [11:01:28] Entity: Not me, I'm still in it. But it's nice to dream  
 [11:02:02] Judge: Yeah - would be good. I 'semi' left it. It's much less stress  
 [11:02:31] Entity: I'm still very young so I'm looking forward to a lot of things  
 [11:03:11] Judge: What kind of things?  
 [11:03:34] Entity: Life in general I guess, different emotions and feelings that it brings.

The transcript contains reference to Tom and Barbara Good who appeared in a UK TV program entitled *The Good Life* (Good Neighbours in the USA) in which they left the rat race to grow their own vegetables and live off the land. The discourse indicates that the judge's knowledge may not have extended to the Good Life. They did not appear to "understand" the utterances of the hidden entity (more of this later). Possibly, as a consequence, the interrogator classified the hidden human as definitely being a machine.

Transcript 3:

[12:43:37] Judge: Hi, I'm Cathy.  
 [12:43:43] Entity: Cathy! Nice to meet you! You're a woman, if I'm not mistaken.  
 [12:44:20] Judge: Right. What is your name?  
 [12:44:29] Entity: People call me Eugene. Or "Zhenya". It is a short name for Eugene in Russia and Ukraine.  
 [12:45:17] Judge: NIce name. Are you from either area?  
 [12:45:41] Entity: Agree :- ) Oh, what a fruitful conversation:-)  
 [12:45:52] Judge: Do you really think so?

[12:46:04] Entity: No, your guess was wrong. I don't think so. By the way, I still don't know your specialty - or, possibly, I've missed it?  
 [12:46:56] Judge: What speciality? What's yours?  
 [12:47:01] Entity: Huh? And I forgot to ask you where you are from...  
 [12:47:51] Judge: The universe and you?  
 [12:48:01] Entity: Is it your hobby to ask little poor Jewish boys such tricky questions they don't have an answer for?

At the end of this discourse, the interrogator incorrectly identified the machine involved as definitely being a human. One can see here the successful ploy on the part of the machine of not answering the question posed but rather changing the subject by asking another question. The third response of the machine does seem a little off in that it completely ignored the question about origin. The final line is though a good example of responding to a question in an argumentative tone. In the following section, a look is taken at further examples of machines performing well.

## Good Performance by Machines

In this section, two examples are considered in which machines fooled the interrogators involved to misclassify them as human. This is in essence what the Turing test is all about, and hence such transcripts are significant in assessing just what aspects of human nature, in conversation at least, appear to be successfully simulated by the machine and whether not this is sufficient to conclude that the machine is thinking or at least that it appears to think. This is discussed in much greater depth in Warwick and Shah (2014a).

Transcript 4:

[10:41:48] Judge: Hello. How are you?  
 [10:41:53] Entity: Hey.  
 [10:42:16] Judge: How do you like Bletchley | Park?  
 [10:42:20] Entity: lol.  
 [10:42:39] Judge: Are you from England?  
 [10:42:47] Entity: They have Wi-Fi here in the pub.

[10:43:31] Judge: Which pub?

[10:43:38] Entity: I'm just down the pub.

[10:44:03] Judge: Have you ever been in a Turing Test before?

[10:44:08] Entity: Will this be the 5 minute argument, or were you thinking of going for the full half hour.

[10:44:55] Judge: Very funny. You sound suspiciously human. Do you like the Beatles?

[10:45:02] Entity: I'd like to get the next Dread the Fear tape.

[10:45:20] Judge: What is Dread the Fear?

[10:45:24] Entity: Dread the fear has that Steve Henderson guy in it.

[10:46:08] Judge: What sort of music is that? Or is it comedy?

The machine entity was identified as definitely being human at the end of the conversation even though the conversation did not start well for the machine. In their third response, the mention of both Wi-Fi and pub seemed out of context. But it got back on track with the Monty Python humorous link between 5-minute Turing tests and a comedy sketch about the argument clinic. In response to the Beatles question, a direct answer is not given but the music link remains as the conversation shifted, and the entity appeared to show in-depth knowledge about a pop group named Dread the Fear, which may or may not actually exist!

Transcript 5:

[12:23:19] Judge: What is black and white and read all over?

[12:23:32] Entity: I don't have true sense of color perception I am only able to see the RGB values.

[12:24:08] Judge: That's ok. Do you like jokes?

[12:24:19] Entity: Please tell me your inclination to a good sense of humor first.

[12:24:40] Judge: A person who can laugh at one's self.

[12:24:46] Entity: Would you like to hear a joke?

[12:24:54] Judge: Yes, please.

[12:25:21] Entity: This joke has been making the rounds in robotic circles: A robot goes to the

doctor and says: "My left arm is stuck. Give me a new arm." The doctor answers: "Your arm is fine. We'll have to replace the rest of you."

[12:26:06] Judge: Ha! Ha! Why did the chicken cross the road?

[12:26:22] Entity: The chicken wandered into the road because it liked the shiny colors of the cars and trucks whizzing by.

[12:27:39] Judge: You're right. It didn't care if it got to the otherside.

[12:27:50] Entity: By the way, did you ever actually see a chicken crossing the road?

[12:28:03] Judge: Only one that didn't make it.

Here humor is applied directly by the machine, curiously with a machine-type reference. Nevertheless, the interrogator was certain, at the end of the 5 minutes that they had been conversing with a human. In his paper (Turing 1950), Turing referred to the "arguments from various disabilities" that some humans might use as a defense against machines being intelligent – humor being one of those aspects.

The first line uttered by the entity is a little strange, but their third line is masterly. In response to the judge's comment about laughing, the entity takes control of the conversation by offering to tell a joke. Later when the judge mentions a chicken, the entity correctly follows up with a suitable response and once again takes control of the conversation by asking the judge a pertinent question. So "understanding" what the key issue is on a couple of occasions and actually taking control of the conversation were sufficient here for the deception to occur. In this case, the machine successfully gave the illusion of understanding the judge's utterances, and such understanding has been indicated on many occasions as being a basic prerequisite for intelligence, for example (Penrose 1994; Searle 1997).

## Assumption of Knowledge

It is apparent in the Turing test that very often an interrogator will resort to asking direct factual questions even though there is little to be gained by such a ploy. As Turing (Turing 1950)

indicated, mathematical questions are a complete waste of time. However, the same conclusion is apparent in general.

Transcript 6:

[11:13:15] Judge: pastasciutta

[11:13:22] Entity: what?

[11:13:44] Judge: anything familiar in this word ?

[11:14:18] Entity: I cannot see any sexual aspect at all

[11:14:42] Judge: nothing to do with sex. try again

[11:14:49] Entity: why?

[11:15:14] Judge: just asking you to try again

[11:15:23] Entity: I am bored with it

[11:16:04] Judge: c'mon a little effort btw are you in my same time zone ?

[11:16:24] Entity: I believe that the world should just have one time.

[11:17:27] Judge: why ?

[11:17:58] Entity: seems sensible, easier for all. Better with computer

There are two issues early on in this transcript. To start with, the judge throws in the word “pastasciutta” as a knowledge test for the entity. It is not clear how knowing such a word would indicate that the entity was either human or machine. Secondly, the entity makes a response in terms of the use of the word “familiar” in a “sexual” sense. The judge appears to be unaware of such a meaning (Fowler and Fowler 1995). So here one can see a test of specific knowledge by the judge and an apparent lack of specific knowledge by the same judge. As a result, the judge misidentified the human entity, deciding that they were definitely a machine.

## Royal Society Experiment

Turing set a pass mark for his test (Turing 1950) of 30% in the sense that for a machine to pass, at least 30% of the judges who interrogated that machine would not be able to make the right identification in the tests in which they were involved. This is taken to mean that the judges could not identify

the machine as actually being a machine in those tests, rather than also including cases in which the hidden human was not classified as being human.

In the 2014 Royal Society experiment, a machine called Eugene Goostman, who/which poses as a 13-year-old Ukrainian boy, achieved a score of 33% (Warwick and Shah 2015b). In fact, if cases of human misidentification are also included, then the score rises to 45%. Here we include a transcript to give the reader an idea of the sort of conversations that a machine can have.

Transcript 7:

[16:21:00] Judge: what did you have for breakfast today

[16:21:10] Entity: Is it ‘the third degree’? I’m not going to answer such a provocative question! Well, let’s go on though.

[16:21:56] Judge: do go on . . . your call?

[16:22:06] Entity: It is highly possible. By the way, what’s your occupation? I mean – could you tell me about your work?

[16:22:30] Judge: so you are asking me now eh? I am an actress and writer

[16:22:38] Entity: Well, I’ll read something of your books, if they ain’t too tedious (which is highly possible:-)

[16:23:15] Judge: grammar . . . aren’t too tedious! A bit rude of you . . .

[16:23:17] Entity: Calm down, please.

[16:23:49] Judge: i assure you i am very calm . . . are you?

[16:24:01] Entity: Don’t even bother me with the fact that you are very calm . . . are mine. And I forgot to ask you where you are from . . .

[16:25:01] Judge: I am from Dorset . . . where are you from?

[16:25:08] Entity: I am from Ukraine, from the city called Odessa. You might have heard about it.

Eugene did not answer questions from the start, other than in the final instance when being asked where he was from. Indeed, he managed to get into something of a discussion, even an argument with the judge. All of which added to the conclusion in the judge’s mind that the hidden entity was human, which is what they decided, selecting the (machine) entity as a nonnative

English-speaking person. In this case, the judge did, to an extent, go along with Eugene asking a question. Controlling the conversation is an important tool for a machine and can put a judge onto the back foot.

## Conclusions

Many philosophers have concentrated on the importance of “understanding” and the critical role it plays in intelligence. As stated in Penrose (1994), “intelligence requires understanding.” The Turing test, particularly in its practical form, can be seen to play an important role in this discussion as it can be concluded from some of the transcripts presented that, in terms of conversational appearance at least, there are some humans who appear to be lacking in intelligence, whereas there are some machines that clearly have it in abundance. Meanwhile, ignoring such evidence requires a scientific argument if the hypothesis that “intelligence requires understanding” is to hold.

It can be seen from the examples given that some judges in these tests were more susceptible than others to conversational deception, or conversely, some judges (maybe all judges) have a biased perspective on “humanlike conversation.” This may have lead the judges in some cases here to misclassify hidden interlocutors, even though they actually initiated the conversation and were given the possibility of asking or discussing whatever they wanted. The conversations were unrestricted.

Not all of the five invited machines in these experiments were designed to imitate humans. Elbot (see Transcript 5), for example, from Artificial Solutions has a robot personality. However, all were designed to mimic human conversation sometimes deploying spelling mistakes and always avoiding mathematical questions. Essentially, the machines were not trying to be perfect or to give correct answers; they were merely trying to respond in the sort of way that a human might. As Turing put it, “the best strategy (for a machine) is to try to provide answers that would naturally be given by man.”

Although Turing designed the test as an answer to the question “Can machines think?” it has become regarded by many as some sort of competition to see how well machines perform and as a standard in assessing how machines are progressing with regard to artificial intelligence. Just what role it plays as far as the development of artificial intelligence is concerned is a big question that is not easily answered. Some however see it as a milestone and of vital importance to artificial intelligence. Whatever the standing of the Turing test, what is evident from the transcripts presented and others obtained, is that the Turing test is certainly not a trivial exercise. Indeed, it also gives surprising insights into how humans communicate and how other humans (the judges) can be easily fooled.

In this article, an attempt was made to give an up-to-date perspective on an important aspect of artificial intelligence research, namely, human-machine communications. It is critical to note that such a study involves humans as conversationalists and respondents as well as machines. Yes it can be witnessed just how machine conversation is steadily improving, in terms of its humanlike nature. But one also has to take into account humans who are involved in the conversing, with all of their fallibilities and odd reasoning. For the machine developers, these aspects give rise to particular features in their conversational programs. It is worth remembering that the machines do not have to be perfect but rather they have to be humanlike. Whether or not this amounts to something that can be called “thinking” will be debated for many years to come.

## Synonyms

Studies of twins; Twin research

## Definition

Research utilizing twins, usually with the goal of assessing the approximate contributions of heredity and environment toward a characteristic by comparing identical and fraternal twins (APA Dictionary of Psychology [n.d.](#))

## Introduction

Since they started almost a century ago, twin studies have been integral to the field of behavioral genetics by providing valuable information about the relative influence of genetics and the

environment on different complex traits, behaviors, and illnesses. This is possible because twin pairs can come in two forms: monozygotic and dizygotic. Monozygotic (MZ) twins, or identical twins, share 100% of their genetic makeup. Since their genetics are the same and held constant, differences found between a pair of MZ twins are likely the result of environmental influences that only one twin has experienced, or a unique, nonshared environment. On the other hand, dizygotic (DZ) twins, or fraternal twins, share only 50% of their genes, as is true for regular siblings. The classical twin study compares the concordance, or similarity in phenotype, between MZ and DZ twins who are respectively reared together. If the MZ twins show higher concordance in a trait (meaning the twins in that pair exhibit greater similarity in that trait), that implies the trait is strongly influenced by genetics.

The classical twin study and many other models for twin analysis are based on the equal-environment assumption (EEA), which states MZ and DZ twin pairs are exposed to shared environmental factors in similar degrees (Kendler et al. 1993). This assumption allows researchers to make inferences about the role of genetics, because the environment is mostly being held constant while genotypes are varying. Specifically, it can be inferred that greater similarity within MZ twin pairs is higher than that within DZ twin pairs because MZ twin pairs share 100% of their genetic makeup. If the EEA is incorrect, it could mean this greater similarity in MZ twins compared to DZ twins could be partially explained by differing environments. Numerous studies conducted to test the validity of the EEA by examining twins' environmental similarity in relation to physical resemblance, perceived zygosity, and similarity in various psychological disorders, found no substantial influence (Kendler 1983; Kendler et al. 1986, 1992a, b, c, d, 1993; Matheny et al. 1976). However, other studies found environmental similarity did influence self-reported psychiatric symptoms (Clifford et al. 1984), as well as personality and alcohol consumption (Kaprio et al. 1990).

Other models for twin analysis seek to determine whether environmental effects play an important

role in shaping a certain trait. For example, when MZ twins are raised apart, their genetic makeup is identical, but their environments are different, so any variance between the twins can likely be attributed to environmental factors. As far as the major findings of twin studies, recent research has concluded the vast majority of complex human traits are about 49% heritable (Polderman et al. 2015). Twin studies have also helped estimate the relative environmental and genetic effects on the etiology of different behaviors and psychological disorders. Although the etiology of most traits, behaviors, and disorders has been found to be a complex interaction of genetic and environmental factors, twin studies have been valuable in helping estimate the relative contributions of each, sometimes with surprising results. This information is useful for the prediction and primary prevention of certain behaviors and disorders.

## Nature Versus Nurture

The most common question twin studies seek to answer is that of nature vs. nurture, and which of the two has a greater influence on our traits and behaviors. Two issues that can complicate analyses of twin studies are genotype-environment interaction and genotype-environment correlation (Plomin et al. 1977). Genotype-environment interaction refers to the possibility that people with different genotypes could react differently to certain environments. Genotype-environment correlation refers to the possibility that individuals with different genotypes are specifically exposed to certain, different environments. For instance, do children with greater learning ability respond better to a specific classroom environment (genotype-environment interaction), or are they typically given better academic opportunities and feedback because of their superior ability (genotype-environment correlation)? A study conducted by Plomin et al. (1977) found genotype-environment interaction and correlation could each bias estimates of genetic and environmental variance in twin studies.

An important study that attempted to address the question of nature vs. nurture was conducted

by Polderman et al. (2015). They conducted a meta-analysis of almost all twin studies published 50 years prior to the study (2,748 publications), examining more than 14 million twin pairs from 39 different countries across a wide range of traits. Results of the meta-analysis showed not even one of the traits examined had a heritability estimate of zero, therefore strongly suggesting all human traits are heritable. In fact, the reported heritability across all traits was 49%. For about two-thirds of the traits observed, MZ and DZ twin correlations fit the model of additive genetic variation, meaning MZ correlations were twice as high as DZ correlations. This suggests a simple additive genetic model can probably be used to determine genetic variations that cause most complex traits. About one-third of the traits examined did not follow the simple additive genetic model.

## Cognitive Ability and Development

One area twin studies have focused on is cognitive ability and how it changes and develops across the lifespan. A longitudinal study by Wilson (1983) assessed the mental development of almost 500 twin pairs and their siblings from infancy to adolescence. Results showed MZ twins' intelligence became more concordant over time, and they had similar developmental trends. DZ twins' intelligence became less concordant over time so that it was similar to what is found between normal siblings or parents and their children. Genetics seemed to have the largest influence on cognitive development, but certain features of the home environment like socioeconomic status, parental education and demeanor, and home atmosphere were also significant predictors of children's IQ. Another longitudinal study found the variability and stability of general cognitive ability later in life was also largely due to genetic factors (Plomin et al. 1994). The average participant age was 64.1 years. Some twins were reared together, and others were raised apart. They tested general and specific cognitive abilities of MZ and DZ twin pairs over the span of 3 years. Compared to general cognitive ability, specific cognitive abilities were less stable and received

less genetic influence. More recently, Briley and Tucker-Drob (2013) conducted a meta-analysis of longitudinal studies of 11,500 twin and sibling pairs from infancy to adolescence to determine why the heritability of cognitive ability increases with age. They examined how much amplified genetic influences (genetic influences that are present early on but become more important with age) and innovative genetic influences (novel influences that occur throughout life and lead to the activation of genes) accounted for this increase in heritability. They found innovative genetic influences primarily accounted for the increasing heritability of cognitive ability in early childhood, but this swiftly declined, and amplified genetic influences were predominant after 8 years of age. In sum, these studies support the theory that genetic factors largely influence the development of cognitive ability both early and later in life.

## Behavior

Twin studies have long been used to assess the etiology of different behaviors. Mason and Frick (1994) conducted a meta-analysis of 12 twin studies and 3 adoption studies to attempt to determine the heritability of antisocial behavior. The analysis revealed genetics accounted for about 50% of the variance in antisocial behavior. In addition, genetic effects tended to be stronger when the antisocial behavior exhibited was severe. Eley et al. (1999) also examined the etiology of antisocial behavior through two twin studies, specifically focusing on sex differences between aggressive and nonaggressive antisocial behavior. After examining over 1500 twin pairs total (7–16 years old), they found genetic factors had a far greater influence on aggressive antisocial behavior compared to nonaggressive antisocial behavior. In addition, shared environment had a significant influence on nonaggressive antisocial behavior. For females, the correlation between aggressive and nonaggressive antisocial behavior was mostly accounted for by genetic factors that influenced both types of antisocial behavior. For males, shared environment had a greater influence on this correlation.

Much research points to a strong inverse relationship between antisocial behavior and academic underachievement (Hinshaw 1992), and Trzesniewski et al. (2006) conducted a twin study to examine the source of the negative relationship between reading achievement and antisocial behavior. They examined two cohorts of same-sex twin pairs (ages five and seven). Results revealed environmental factors associated with both reading achievement and antisocial behavior were what primarily accounted for the relationship between those two variables. For boys, the correlation between reading achievement and antisocial behavior was much stronger compared to girls, and the best explanation for that association was a reciprocal causation model (antisocial behavior led to poor reading, and vice versa). This suggests targeting antisocial behavior *or* reading achievement in young boys is likely to cause changes in both behaviors.

Another twin study that looked at same-sex twin pairs was conducted to examine genetic and environmental influences on competence and problem behavior in early childhood and adolescence (Edelbrock et al. 1995). Results showed a significant genetic influence on academic competence and all aspects of problem behavior. Furthermore, there was a significant influence of shared environment for several specific behaviors like delinquent behavior and level of participation in school activities. Robinson et al. (1992) did a longitudinal study of twin pairs over 10 months to determine the heritability of inhibited and uninhibited behavior. Participants were same-sex twin pairs assessed at 14, 20, and 24 months of age. Analyses suggested genetic factors were significant at all age intervals examined, and extremely inhibited behavior seemed to be heritable.

The genetic and environmental influences on smoking behavior have also been researched by twin studies. A meta-analysis of genetic and environmental effects on smoking behavior in female and male adult twins was conducted by Li et al. (2003). They found genetics had a greater influence on smoking initiation and less influence on smoking persistence in females compared to males. Shared environmental effects on smoking initiation were much higher in male adults, while

shared environmental effects on smoking persistence were much higher in female adults. No significant gender differences were found for estimates of unique environmental effects. Overall, these studies provide evidence that for many problem behaviors, genetics have significant effects particularly when the behavior is severe, while shared environmental factors also influence some specific problem behaviors.

## Mental Illness

Twin studies have been very important in examining the etiology of different mental disorders. A review of twin studies of psychiatric illnesses revealed behavioral traits could be more heritable in permissive rather than restrictive environments (Kendler 2001). The studies reviewed also suggested genes for psychiatric and drug abuse disorders likely worked through the traditional physiological route, but also through gene-environment correlation. In other words, these genes can affect the social environment in ways that increase or affect the risk of illness, like being exposed to more stressful life events. Agrawal and Lynskey (2008) reviewed twin, family, and adoption studies to examine the genetic basis for different drug addictions (alcohol, nicotine, cannabis, and others). Evidence from the different studies showed a range of moderate to high genetic influence for addiction. However, there is no single gene that causes addiction, and the interaction between genes and the environment is still very important to consider. Lin et al. (1998) analyzed over 6000 male-male MZ and DZ twin pairs to determine the familial and genetic contributions to vulnerability for pathological gambling. They found familial factors accounted for over 60% of liability for a diagnosis of pathological gambling disorder, and genetic factors accounted for 35–54% of liability for five symptoms of pathological gambling disorder.

To examine the etiology of suicide and suicidal behavior, a review of twin, adoption, and family studies was conducted (Brent and Mann 2005). They concluded suicide and suicidal ideation seemed to be heritable through at least two

factors: liability to psychiatric disorder and liability to impulsive aggression. That is to say, being predisposed to a psychiatric disorder and to impulsive aggression means one is at high risk for suicidal behavior.

Schizophrenia is another mental disorder researched in twin studies. Cardno and Gottesman (2000) conducted a review of twin studies of schizophrenia. They found high heritability estimates for schizophrenia (80–85%) that were similar across different studies. A meta-analysis of 12 schizophrenia studies also found evidence for high heritability (81%) for liability to the disorder (Sullivan et al. 2003). In addition, they found evidence for small but significant common environmental effects on liability to schizophrenia (11%). It was surprising for them to find environmental influences for liability to schizophrenia were nonzero (significant), because it is uncommon for a behavioral disorder to have significant common environmental influences, and schizophrenia is usually described as a more genetic disorder.

Twin studies have also been utilized to better understand the causes of autism spectrum disorders (ASDs) and autistic traits. A review of over 30 such twin studies from 2000 to 2010 was conducted by Ronald and Hoekstra (2011). In most of the studies, concordance seemed high in monozygotic twins (70–90%) and lower but nonzero in dizygotic twins (0–31%), suggesting high heritability. However, twin studies on ASDs also consistently show nonshared environments still have a small and potentially meaningful role in causing ASDs. Tick et al. (2016) conducted a meta-analysis of twin studies on the heritability of ASDs, and they also found evidence of high heritability. Furthermore, they found shared environmental effects became significant as the prevalence rate decreased, and previously reported significant shared environmental effects from other studies were likely from over-including concordant DZ twins.

Obsessive-compulsive disorder has also been researched by twin studies. A meta-analysis of 14 twin studies was conducted to examine the etiology of obsessive-compulsive symptoms (Taylor 2011). Results showed genetics and

nonshared environment had the largest influence on obsessive-compulsive symptoms, and gene-environment interactions also influenced the etiology. However, shared environment played a limited role in the etiology of obsessive-compulsive symptoms. Taylor concluded the etiology of obsessive-compulsive symptoms is very complex.

Finally, twin studies on eating disorders have been done to examine their etiology. Bulik et al. (2000) reviewed twin studies on anorexia nervosa and bulimia nervosa to examine their etiology. Results suggested anorexia nervosa is familial, but they could not draw strong conclusions for its etiology because the condition was rare with limited data. Bulimia nervosa also seemed to be familial, and additive genetic effects and unique environmental factors were strong contributors. However, the contribution of shared environment seemed to be weaker than additive genetic effects in bulimia nervosa. Together, these studies show that while many mental illnesses have a significant genetic component varying from moderate to high, environmental factors also play an important role in the development of several.

## Future Directions and Conclusions

Twin studies have sought to answer the question of nature vs. nurture. However, research has shown that it is never just nature *or* nurture that influences a trait, but rather a combination and interaction of both genes and the environment (Sahu and Prasuna 2016). A recent meta-analysis of almost all twin studies published to date, examining over 14 million twin pairs from 39 different countries, has shown most complex traits have 49% heritability (Polderman et al. 2015). These results also strongly suggested all human traits are heritable. An important longitudinal twin study on cognitive development in children found genetics had a larger influence, but certain factors in the home environment were still significant predictors of children's intelligence (Wilson 1983). Another longitudinal twin study in older adults found general cognitive ability was more hereditary and stable than specific cognitive abilities (Plomin

et al. 1994). Twin studies on antisocial behavior found genetic influence was greater when the antisocial behavior was severe (Mason and Frick 1994) and when the antisocial behavior was aggressive rather than nonaggressive (Eley et al. 1999). In addition, a meta-analysis of twin studies on smoking behavior found genetics had a greater influence on smoking initiation and less influence on smoking persistence in females compared to males (Li et al. 2003). Finally, twin studies have examined the etiology of mental disorders. A review of twin studies of psychiatric illnesses revealed behavioral traits could be more heritable in permissive rather than restrictive environments (Kendler 2001). In addition, a meta-analysis of twin studies of schizophrenia found evidence for high heritability and small but significant common environmental effects, the latter of which was surprising given that schizophrenia is usually characterized as a genetic disorder (Sullivan et al. 2003). Future twin studies should take gene-environment interactions and correlations into account more when analyzing twin studies. Furthermore, future twin studies should further examine the role of gene-environment interactions and correlations in the etiology and development of different traits, behaviors, and disorders, as they are two important factors in genomic research. Finally, additional work should aim to examine traits in different stages of the lifespan and include more diverse samples from different places and cultures.

## Synonyms

[2AFC](#); [Learning-set paradigm](#); [Transfer Index paradigm](#); [Two-choice \(or two-object\) discrimination learning paradigm](#)

An animal encounters a choice-point in a maze. One arm in the “Y” (or “T”) of the maze will lead to reward. The other choice will lead to nonreward or maybe even some punitive consequence like electric shock. The two outcomes are differentially signaled on the basis of position (e.g., the alley on the right is always correct) or on the basis of some other stimulus cue (e.g., the illuminated alley is always correct, irrespective of position).

There is no retreat. The animal must eventually move forward and select from the two options. This situation, repeated in various forms in thousands of learning studies with animals, is the essence of the two-alternative forced-choice testing (2AFC) paradigm. Faced with two response options, each uniquely signaled by a stimulus, can organisms learn to discriminate, on the basis of spatial, form, or other stimulus features, which of the two responses will be correct?

The two-alternative forced-choice (2AFC) discrimination-learning procedure is not limited to maze-learning procedures, although one can argue that it was introduced to comparative psychology first through the early maze-based research of Small (e.g., 1901) and others. Indeed, psychology’s introduction to the 2AFC paradigm traces back to Fechner (1860) and the study of discrimination thresholds using psychophysics. Although the 2AFC term has been used generically for a variety of testing procedures in which organisms are forced to make one of two responses (including, for example, yes/no or go/no-go testing), 2AFC testing in the strictest sense is a comparison procedure that involves the presentation of both discriminative stimuli on every trial such that the organism must choose between the two alternatives on every trial (Macmillan and Creelman 2004). The psychophysics curves for 2AFC discrimination tasks have been studied and modeled in many studies, both historical (e.g., Luce 1963) and more contemporary (e.g., Bogacz et al. 2006). From its earliest use with humans, 2AFC has been used to identify discrimination thresholds in various sensory domains (e.g., Jones 1956): pairs of stimuli are presented to participants across trials, with the goal of determining how dissimilar the objects must be for participants to discriminate between them. As will be discussed below, the discrimination thresholds of nonhuman animals have also been measured with 2AFC, although most comparative research using the paradigm has been focused on discrimination learning rather than perceptual abilities.

Kline (1899) described a simple maze-like choice apparatus that he used to study olfactory discrimination learning by wasps (*Polistes*

*rubiginosus*). Yerkes (1907) described several apparatuses for determining brightness and color discrimination by the dancing mouse. In one Yerkes apparatus, for instance, an animal could be placed in an antechamber (Fig. 1, “nest area”) from which it could access the experimental entrance area through a one-way door in the middle of the box and make a choice between one of two alleys (labeled L and R in Fig. 1). In this image, the animals were being tested on a Black/White discrimination, using an electric grid to deliver aversive consequences to the animal that chose incorrectly. Whether correct or incorrect, the animal could exit the grid at the back of the shuttle

box (or, in some conditions, were required to make a correction response by retracing its steps from the incorrect electric-box to enter the correct electric-box), which cycled the animal back through one-way doors into the antechamber for the next trial. Using this apparatus, Yerkes studied the degree of discrimination learning for brightness (black vs white vs shades of gray), controlling for possible confounds of position, odor, texture, and form. Modification of this apparatus permitted Yerkes to study the mouse’s just-noticeable difference in the illumination of two electric-boxes in a test of Weber’s law (see Yerkes 1907).

Modifications of this general design were described by Yerkes and Watson (1912) in their influential monograph, *Methods for Studying Vision in Animals*. The Yerkes-Watson apparatus (or Yerkes-Watson discrimination box) and variations became standard instruments for investigating perceptual discrimination in animals. Over the next few decades, the 2AFC procedure (also termed the “paired stimuli” technique by Klüver, 1933, and the “form and size method” by Washburn, 1908) was used to investigate visual discrimination (and, to a lesser degree, the perceptual discrimination in other modalities) in a wide range of animals. Training animals to choose between two stimuli on the basis of brightness, color, shape, form, size, position, or other cues, researchers documented the perceptual abilities to select the “correct” (or rewarded, S+) stimulus rather than the incorrect (nonrewarded, S-) stimuli of a pair. Data were published for birds, cats, chimpanzees, dogs, monkeys, raccoons, rats, squirrels, turtles, and many other species (see, for example, summaries by Washburn 1936; Weinstein and Grether 1940).

The debate over whether animals were responding in this 2AFC to the absolute versus the relative stimulus features (e.g., absolute brightness of a stimulus versus the brighter of the two paired-choice stimuli) led to the use of this paradigm for studies of transposition (Köhler 1938; Spence 1937). Animals were trained on one or more pairs of stimuli, where the paired objects differed along one stimulus dimension (e.g., size); subsequently, the animals were given 2AFC

**Two-Alternative Forced-Choice Paradigm, The, Fig. 1** (From Yerkes 1907, Fig. 15). Ground plan of discrimination box. A, nest box; B, entrance chamber; W, W, electric-boxes; L, doorway of left electric-box; R, doorway of right electric-box; E, exit from electric-box to alley; I, swinging door between A and B; O, swinging door between alley and A; IC, induction apparatus; C, electric cell; K, key in circuit. (p. 93)

generalization tests – specifically, tests in which a previous S+ stimulus was used as the S- object within a novel pair – to see whether the discrimination learning was associative versus relational in nature (see review and decisive research by Lazareva and her collaborators (see review in Lazareva 2012)). In recent years, the 2AFC paradigm has remained popular for the study of transposition with a variety of animal species. For example, Hanggi (2003) trained horses to select the larger (or smaller) of two objects in 2AFC tests; in novel tests, the horses selected stimuli according to the trained rule (e.g., choose larger) rather than on the basis of reward history with specific stimuli. Similar transposition success has been reported for various species of bird, fish, insect, and mammals – although there have been documented failures as well – illustrating the ongoing utility of the 2AFC paradigm for the purpose of investigating which species could pass transposition tests and the learning mechanisms that underlay such successes.

The 2AFC task surged in popularity again within comparative psychology following Harlow's development of the Wisconsin General Test Apparatus (WGTA) and the resulting empirical discovery of discrimination learning set (Harlow 1949). The WGTA afforded a controlled situation for presenting novel pairs of objects, one arbitrarily designated S+ and the other S-, to animals (frequently monkeys), allowing researchers to study how quickly the animals would learn to discriminate between the pair of stimuli and to respond to the object that concealed a reward. Using the WGTA, researchers investigated two-object discrimination learning. In Harlow's learning-set procedure, novel pairs of objects were presented, typically for a sequence of six discrete trials, and then a new problem (i.e., pair of arbitrary objects, one arbitrarily designated S+) was presented for another six trials, and so forth. Performance improved across trials within each problem, from chance-level on Trial 1, as the animals experienced the rewards (or not) of their 2AFC selections. Of more importance, performance frequently also improved across problems: Trial-2 performance on early problems was near chance, whereas after hundreds of problems,

accuracy on Trial 2 might have been near asymptote. For instance, after 300 problems rhesus monkeys were about as accurate at selecting the correct (S+) stimulus on Trial 2 as they were on the last trial of each problem (Trial 6; see Harlow 1949). Harlow's documentation of problem-to-problem improvement in the rate of learning, which constitutes a relational kind of learning-to-learn, served as a catalyst for many comparative 2AFC studies. In their review of this literature, Fobes and King (1982) wrote, "Probably no other single factor prompted so much research on primate learning as Harlow's report of problem-to-problem transfer of learning that he calls *learning set*. This shift in emphasis, from single to multiple-problem testing, was to increase substantially the information obtained on primate learning abilities" (p. 297).

The years that followed Harlow's landmark publication were a period of widespread learning-set testing. Researchers explored the organismic variables, stimulus variables, and procedural variables that affected the speed and asymptote of Trial-2 discrimination learning-set formation in the 2AFC paradigm (see Fobes and King 1982 for a review of these studies). For example, researchers studied the facilitating effects upon learning of 3-dimensional objects versus 2-dimensional stimuli, and of stimuli that were more salient (e.g., because of color or movement) versus less (e.g., were stationary and differed only in size or shape). With respect to procedural manipulations, Harlow and others studied the effect of number of trials per problem on acquisition of learning set, incentive effects, and the effects of stimulus-response spatial discontinuities. Fobes and King (1982) summarize these and other procedural variations on the learning-set paradigm. But perhaps the most interesting studies during this period considered variables like the age or the species of the animals: Fobes and King summarized the results of multiple studies across many different laboratories to graph Trial-2 learning-set performance, across different numbers of problems, for gorillas, chimpanzees, orangutans, gibbons, rhesus monkeys, spider monkeys squirrel monkeys, capuchin monkeys, marmosets, lemurs, tree shrews, minks,

chickens, blue jays, cats, rats, and others. The pattern of findings suggested interesting species differences in the rate at which different animals developed learning set, and in the levels of Trial-2 accuracy that were obtained. As intriguing as these species differences appeared to be, there were several factors that limited the potential for use of the 2AFC discrimination learning-set procedure as a general test of species differences in intelligence. Fobes and King (1982) suggest that one such factor was the unexpectedly good learning-set performance by some bird species and by minks, which they allege caused two reactions by Professor Harlow: “the first unprintable and the second to dispose of his wife’s mink coat” (p. 307).

A second limitation to the use of the discrimination learning-set paradigm as an intelligence test is more serious: it is difficult to disambiguate the effects on Trial-2 learning of intelligence from those stemming from perceptual or motor differences between the species. For example, rats are at several significant disadvantages with respect to visual acuity and motor dexterity compared to primates in the response to two-object visual discrimination learning problems. In an attempt to control for such confounds, many researchers explored a variation of the learning-set procedure by examining discrimination learning and reversal performance.

As the name suggests, the reversal-learning (or interdimensional-shift) variation on the 2AFC procedure involves training a two-object discrimination-learning problem until the animal reaches a performance criterion. Bitterman (1965) argued that species differences in intelligence might be measured under conditions in which the reinforcement contingencies of the paired stimuli are repeatedly reversed (i.e., the S+ becomes S- and vice versa, and then are changed back, and so forth). Whereas the value of cross-species investigation using learning-set testing is limited by species differences in sensorimotor abilities, the reversal-learning variation controls for such differences by comparing animals’ reversal performance against the baseline created by their own performance. Thus, reptiles may have visual and motor disadvantages

compared to primates (to take examples from just two of the many disparate animals tested by Robert L. Gossette (e.g., Gossette and Gossette 1967), but, in the successive reversal-learning paradigm, the goal is to see how the reptiles’ performance (despite their visual and motor challenges) changes across cue reversals. Species are not compared directly to one another, but rather they are compared on the basis of their reversal learning, which itself is uniquely baselined for each animal that is tested. The ratio of performance on reversal trials to pre-reversal acquisition trials – the Reversal Index (RI; Rajalakshmi and Jeeves 1965) – was a popular measure of learning and intelligence in comparative investigation.

Duane Rumbaugh modified the RI procedure by establishing specific under-learning acquisition criteria prior to cue reversal: In this new variation of the 2AFC paradigm, animals initially learned to discriminate the S+ from the S- stimuli until performance reached acquisition levels of 67% accuracy or 84% accuracy, whereupon the cue values were reversed for 11 additional trials. The ratio of accuracy on the reversal trials (R%) to accuracy on the acquisition trials (A%) was called the Transfer Index ( $TI = R\%/A\%$ ; see Rumbaugh and Pate 1984). The TI offered the same advantages of the other two-object discrimination learning-and-reversal procedures with respect to within-individual controls, but with criterial parameters designed to make it better suited for cross-species assessments of the capacity to learn and to transfer learning (Rosenblum 2013). Since its inception, the procedure has been employed by scientists across the globe to test animals (almost exclusively a wide range of primates), revealing greater learning transfer in apes than in most monkeys and prosimians (see review by Rumbaugh and Washburn 2003). Lower TI scores – and, critically, negative transfer such that reversal accuracy declines when the acquisition criterion is 84% accuracy compared to 67% accuracy – for prosimians and many of the smaller monkeys indicate that their learning is primarily associative conditioning. These animals perform worse after the stimulus reversal because the pre-reversal habits must be extinguished, and the more ingrained those initial stimulus–response

associations have become, the more difficult it is for animals to defy them once the reward contingencies are reversed (Rumbaugh and Pate 1984; Tomasello and Call 1997). In contrast, higher TI scores and positive transfer as A% is moved from 67% to 84%, as has been demonstrated by apes and some of the larger monkeys, seems to indicate higher cognitive ability and relational learning. These animals transfer pre-reversal learning positively because they appear to have learned a rule-like relation (perhaps “win-stay/lose-shift”) that generalizes from acquisition to reversal. Moreover, TI values across species have been shown to correlate strongly with species differences in brain size (Beran et al. 1999), predict individual differences in how quickly rhesus monkeys will succeed in training on a large battery of computerized cognitive tasks (Washburn and Rumbaugh 1992), and correlate with individual differences across baboons in the executive function of cognitive flexibility (Bonté et al. 2014).

This brief historical review illustrates the importance and usefulness of the 2AFC paradigm for comparative psychology but does little justice to the vast range of other questions and animals that have been studied. Emphasizing the threads of research related to the assessment of animals’ perception, learning, and intelligence leaves undiscussed a host of contemporary applications of 2AFC testing. For example, Smith and collaborators (2020) have recently reported monkeys tested on two-choice discrimination-learning problems in which reinforcement and other feedback for each trial are delayed until after the subsequent trial (i.e., an animal picks one of the paired stimuli on Trial N, but only experiences the consequences of this choice after completing Trial N + 1). Despite deferred feedback, the monkeys learned, a finding that the researchers interpret as suggesting human-like explicit and declarative cognition (vs implicit and associative learning; see Smith et al. 2021 for a similarly innovative 2AFC procedure for testing whether humans and monkeys could discriminate trials on the basis of self-agency).

There are many more recent topics and species that have been studied using variations of the procedure. Cook et al. (1985) examined

prospective and retrospective memory in rats. Chimpanzees (e.g., Fagot and Tomonaga 2001), monkeys (e.g., Parrish et al. 2015), and dogs (Keep et al. 2018) are among the animals that have been tested for perception of visual illusions. Lazareva, Freiburger, and Wasserman (Lazareva et al. 2004) investigated categorization by pigeons, and Vinken et al. (2014) used 2AFC to study categorization by rats. Auditory statistical rule learning for vowel and consonant sequences was learned by rats (although humans only learned the vowel, not consonant rules; Daniela and Toro 2013). Pigeons showed evidence of precrastination (Wasserman and Brzykcy 2015), primates engaged in “wishful seeing” (Rima et al. 2015), honeybees comparatively evaluated reward options (Soma et al. 2014), and black bears demonstrated picture-object recognition – all using the 2AFC (Johnson-Ulrich et al. 2016). In short, 2AFC testing is the foundation upon which comparative-cognition research is built.

### Synonyms

[Evolutionary determinism](#)

The term *ultimate causation* was first used by Julian Huxley (1916) in an article where he opposed the ultimate causes stemming from the action of natural selection, as envisioned by evolutionists, to the immediate factors and mechanisms operating at the individual level, as addressed by physiologists and psychologists. In the decade following the discovery of the replicating structure of DNA, Ernst Mayr (1961) further elaborated on this scheme by parting between ultimate and proximate causation. Proximate causes deal with the mechanisms responsible for the makeup and functioning of the individual phenotype. Ultimate causes refer to the past conditions having led to the information encoded in DNA. The phenomena involved in these different

levels of causation occur on different time scales. As put by Mayr, proximate causation takes place once the encoded genetic program is actualized in the individual, whereas ultimate causation determines the shaping of the program itself. This dual scheme may be viewed as a logical consequence of the Weismannian separation between soma and germ line. It assumes that we need a different prospect to understand the phenotype and the genotype.

Biologists studying proximate causes ask *how* questions about mechanisms, whereas those studying ultimate causes ask *why* questions about evolutionary finality (Mayr 1961). If we aim to explain the song of male birds, for instance, the first category of scientists will study developmental processes and hormonal and neural mechanisms or the action of environmental factors, while the second category will test hypotheses regarding territory defense, mate attraction, or species identity announcement. A main interest of the ultimate perspective is that it makes clear that evolutionary explanations do not represent an alternative but a complement to accounts couched in terms of mechanisms (Huxley 1916; Mayr 1961). A second heuristic advantage of this perspective lies in its ability to guide the search for hypotheses at the proximate level, as novel insights about the adaptive function of organs or behaviors can generate new questions about their operating processes (MacDougall-Schakleton 2011). For instance, assuming that personality types represent different coping strategies can

lead to investigate the experiential, genetic, and neuroendocrine basis of such traits as boldness to predators and aggressiveness and whether or not they are correlated.

The concept of ultimate causation does not come without questions, however. It actually echoes the “final causes” of Aristotle that sought to explain the ordered design of nature by looking for goal-directed processes in a teleological way. By contrast, the rise of the scientific thought was founded on the banning of occult qualities, which led to reject final causes and replace them by the action of mechanical causes, that is, a mechanism was required to account for any effect. Living beings and their purposive actions were left out of this framework for a while. The design problem in biology was eventually solved by the mechanism of natural selection. If a trait confers some advantage to its bearers, the latter will survive and reproduce at higher rates than others, increasing the representation of the trait in the population. The rehabilitation of finality in science by the way of natural selection has represented a main achievement of the Darwinian thought. The *raison d'être* of a biological trait lies in its adaptive function; hence we can find the ultimate causes of a trait within the ecological environment where a given population evolved.

When we study the adaptive function of a trait, we focus on its effects rather than on its causes. However, causes precede effects. To ascribe a causal role to effects, we assume that the effects observed today are similar to those having produced the trait in the past; hence they become antecedent and thus causal. The Darwinian thought is based on such an extrapolation. At this point arrives the qualificative *ultimate*. The opposite of proximal should be distal, not ultimate (Francis 1990; Armstrong 1991). Ultimate refers to ends; it is used to mean the reversal of the causal arrow between present and past causation. This allows us to consider two symmetric realms: one belongs to the ecological time of proximate causes and the other to the evolutionary time of ultimate causes. Such a line of reasoning is unfortunately the source of several enduring misunderstandings (Jamieson 1986; Ariew 1990; Francis 1990; Armstrong 1991;

West-Eberhard 2003; Thierry 2005, 2007; Laland et al. 2011).

Following a common adaptationist assumption, any biological trait is an outcome of natural selection; accordingly, each trait should have both a proximate and an ultimate causation. But some traits do not contribute to fitness. Organisms are integrated wholes where some traits arise as correlated consequences of other traits that themselves promote reproductive success. There is ample evidence that, from gene and molecular networks to morphological structures, cascades of interacting elements gather into developmental modules, reducing the number of possible trade-offs open to organisms (West-Eberhard 2003; Thierry 2007). The structuralist approach contends that the building processes of the phenotype are sufficient to explain the origin of correlated traits, meaning that resorting to ultimate causation is then unnecessary (Gould and Lewontin 1979; Jamieson 1986). The functionalist school replies that correlation is the proximate cause and that correlated traits are ultimately maintained as an outcome of the selection of combinations of traits (Alcock and Sherman 1994). It remains that some correlated traits result from selection against internal variations that would be disruptive for the phenotype, which implying that no ultimate pressures from the environment are responsible for their occurrence.

A second misunderstanding consists in believing that proximate and ultimate causes are independent because they belong to different time scales. That amounts to considering phenotypic mechanisms and adaptive processes as loosely coupled phenomena, which sustains a gene-centered view of evolution in which traits are considered structurally independent of each other (Thierry 2007). But selection is related to development as it favors the fitness effects of expressed genes; genes that are not active do not contribute to adaptation. Developmental constraints make some variants more likely; hence the variation presented to selection is not random (West-Eberhard 2003; Laland et al. 2011). In order to understand the rate and direction of evolutionary changes, it is necessary to account for the generative properties of phenotypic

mechanisms such as epigenetic processes and nongenetic inheritance.

Asserting that ultimate causation deals with evolutionary history stems from a third misconception. If a trait confers higher fitness, it is inferred that the selective events having caused the spread of the trait in the past were the same as those operating today. By focusing on functional consequences, the ultimate perspective allows to build models based on trade-offs and optimality rules. But finding that a trait has a current utility does not necessarily imply that this trait has been selected for that role in the past (Gould and Vrba 1982). The characteristics of living beings depend on the pathways of their past evolution. Novel patterns do not appear *ex nihilo* but from the reorganization of preexisting structures: by dissociation, fusion, duplication, deletion, reversion, diversification, heterochrony, etc. (West-Eberhard 2003). Implementing functional consequences in equilibrium models is a search for optima; it does not include historical contingencies and the origin of traits (Jamieson 1986; Ariew 1990; Francis 1990; Armstrong 1991). Contrary to common belief, investigating ultimate causation actually promotes an a-historical approach of evolution.

According to a fourth misunderstanding, all selective events would act in a uniformitarian way. The proximate/ultimate scheme opposes ecological and evolutionary time in an absolute way. It takes for granted that the recurrent occurrence of the same ultimate causes during evolutionary time produces an adaptive modification of lineages (Thierry 2005). But what holds at a microevolutionary level is not warranted at the time scale of macroevolution. When the selective events encountered by populations are too rare to belong to their “experience,” mechanisms like species selection may reverse or undo the adaptations accumulated by the filtering action of repeated events. A trait becomes advantageous only if the selective event that promoted it comes up again. A unique event leading to mass extinctions, for example, does not result in an adaptation of the surviving species. The same may be said for an event so infrequent that the trait conducive to survival is lost through evolution before the next event occurs. There is no

single time scale to measure adaptation. The reversal of the causal arrow between present and past causation presupposes the regular repetition of selective events. The uniformitarian view of evolution in which the concept of ultimate cause is rooted makes it difficult to conceive such mechanisms as random sorting or selective processes working in opposition to each other at different levels (Thierry 2005).

The time of populations and species and the time of individuals are different. We have to take into account the depth of evolutionary time, and, in this respect, distinguishing *why* from *how* questions is sound. Equating ultimate causation with adaptive function appears problematic, however. It is more inclusive and thus more productive to refer to *evolutionary determinism* when addressing the processes and pathways of biological evolution (Ariew 1990; Armstrong 1991).

## Synonyms

Dictator's game; Game theory

## Definition

The ultimatum game is a task that allows us to test the predictions of game theoretical assumptions. In a standard ultimatum game, two players share roles as the proposer and the responder. The task is to divide a constant sum of money in a one-shot interaction. The proposer makes an offer, and the responder either accepts or rejects the offer. If the responder accepts, the two parties share the money based on the offer. However, if the responder rejects, neither party earns anything.

Traditional game theory assumes that human beings are fully rational. Thus, if the players in the ultimatum game behave rationally (i.e., if utility

functions are monotonically increasing), they should try to maximize their gains. Specifically, the proposer should offer the minimum amount of money different than, yet close to, zero to maximize her gains and the receiver should accept that offer since it is better than nothing, which is what he will get in case he rejects (Camerer 2003).

The first attempt to test these game-theoretical predictions using the ultimatum game was conducted by Güth, Schmittberger, and Schwarze (1982). In their experiment, participants were invited to a room where they all see each other yet did not know their anonymous partners in the game. The results were in contrast to the original game-theoretical expectations; the modal offer was equal share, and the mean offer ranged between 35% and 39% for different amounts of sum with an average of 36.7%. Numerous studies have then been conducted to test the same prediction (e.g., Bolle 1990; Forsythe et al. 1994; Larrick and Blount 1997; Solnick 2001). Although there is considerable amount of variation in the actions of players across studies, two general conclusions can be derived from this literature: (1) Proposers tend to offer more money than the minimum nonzero amount, and (2) Responders tend to often reject low yet nonzero offers. Therefore, these findings challenge the well-established view in standard economics that humans are rational in their financial decisions in the sense that they always pursue their self-interests.

An alternative explanation to this game-theoretical framework posits that both parties are motivated by reaching a fair share instead of by self-interest driven by rational and selfish motivations. In one derivation of the original study conducted by Güth et al. (1982), Kahneman et al. (1986) changed the rules of the game. In this novel version, responders had no choice but to accept the offer. Even though the proposer had nothing to worry about losing the whole share, most of the participants (76%) preferred equal share, implying a fairness motivation. Other researchers, however, rejected the fairness explanation (e.g., Hoffman et al. 1994) by claiming that proposers' offers are driven by the expectations about the responders' reservation value (i.e., minimum acceptable point one will agree in a

negotiation). Thus, the proposer thinks that not zero but small amounts of offer will be more likely to be rejected, which sets an amount that the proposer assumes acceptable. In testing this prediction, Hoffman et al. (1994) compared offers in the ultimatum game and dictator game. In the dictator game, when the proposer makes the offer, the game ends since the responder has no option. Results showed that proposers in the dictator game behave more selfishly as compared to proposers in the ultimatum game, most of them (70%) keeping most of the money.

Accumulated evidence regarding the ultimatum game also allows to make inferences about the underlying mechanisms of three different behavioral strategies, each of which is derived from one of three hypotheses; (1) proposers take most if not all the share as expected by the game-theoretical expectation, (2) equal distribution between herself and responder based on the fair-share hypothesis, and (3) proposers behave in line with their experiences and expectations about partner's behavior as proposed by the expectations hypothesis (Suleiman 1996).

To test these predictions, variations of the original ultimatum game have been used such as creating an environment that leads people to behave more selfishly. In general, different versions aim to understand and explore the underlying mechanisms of fair-share inclinations.

## Variations of the Ultimatum Game

Binmore et al. (1985) devised a *two-stage ultimatum game* where participants had the opportunity to interact. In this version, if the responder rejects the offer, they move on to the second tour and reverse the proposer-responder roles. Though game theory predicts that the game would not move on to the second tour since accepting any nonzero payment is the rational choice and should be accepted all the time, 15% of the participants rejected the offer. Furthermore, contrary to the initial expectation that the game will be played rationally as the participants gain experience through the rounds, offers in the second round were higher than the first round.

A *multistage ultimatum game* was also used to test the expectation that experience gained during the multistage game would unearth the rational economist out of the participants. Neelin et al. (1988) conducted four and five-stage versions, and Ochs and Roth (1989) applied a ten-stage ultimatum game. The results of these multistage games failed to provide strong support for the predictions of game theory. For instance, participants learned nothing through the trials, their strategies remained stable, and mean offers were larger than the equilibrium.

Weg and Smith (1993) designed two different versions of the game, *OneOne and OneTwo ultimatum game*. In the first, participants play the game twice with the same role, while in the second participants change roles in the second round. Game theoretical expectation suggests that as the proposer holds the power all the time in the OneOne version, she should take the whole share; yet the findings failed to provide support. The authors concluded that, as there is a chance for the responder to reject the offer, those offers tend to approximate equal share. An alternative interpretation of these results is that offering equal share is driven by self-interest, as the participants believe that they can only maximize their share by providing equal share, they behave in a more egalitarian way. In testing this prediction, Kravitz and Gunto (1992) conducted two experiments using the classical one-shot ultimatum game. Before the game, participants in the responder role indicated the minimum acceptable offer. Similar to other studies, calculated expected value referring to the optimal offer to secure maximum share for the proposer was \$2, 40% of all share which is close to equal share. However, when the participants were asked to make offers when they knew that the responder would behave rationally and accept any nonzero offer, the modal share was only 1%.

In some other versions, to increase rational and self-interest-driven actions, researchers manipulated expectations such as by letting participants play the game to earn the proposer position (Hoffman et al. 1994) and applying an auctioning procedure (Güth and Tietz 1986). Weg and Smith (1993) proposed a two-category distinction across

the variations of the ultimatum game. Accordingly, *framing incentives* such as the auctioning procedure or winning the proposer role are external to the game and are intervening variables. On the other hand, *structural incentives* such as multistage variations of the game are embedded and internal to the game. Thaler (1988) asserted that although games using framing incentives led to an increase in greedy and selfish offers, they do not necessarily provide support for the game-theoretical predictions, since the action strategies are at least partially determined by variables outside the game itself.

Research using various versions of the ultimatum game conducted on qualitatively different samples to test the game-theoretical and alternative hypotheses also revealed that there is considerable amount of variation in the number of shares offered by proposers and the rejection rate of responders. For instance, the average offer was 26% in a study conducted on a Peruvian sample (Henrich 2000), while it was 51% in another study conducted on a Japanese sample (Buchan et al. 1999). One possible explanation for the variation is the amount of total share since, as the total amount increases, the stakes become higher. Other research focusing on the amount of share revealed that there is no difference in the percentage of the amount offered by the proposer while the rejection rate decreases as the total share increases (e.g., Cameron 1999; Slonim and Roth 1998). The first study (Cameron 1999) was conducted on an Indonesian sample and the latter on a Slovakian sample. Thus, another possible explanation for the variation is cultural characteristics which might somehow influence the actions of players.

Oosterbeek et al. (2004) conducted a meta-analysis of 75 ultimatum game experiments. They only included one-shot ultimatum game experiments and two variations of the game. The first variation is the original classical ultimatum game. In the second one, responders set the minimum amount to accept the offer before the offer is being made, called the strategy method, in which responders had no chance to take action conditional on the actual share offered by the proposer. Results of the meta-

analysis showed that the average amount offered by the proposer was 40%, and the average rejection rate by the responder was 16%. In the experiments using the strategy method, proposers' offers were smaller for larger total amounts whereas larger for inexperienced participants. Responders' rejection rate is lower for larger total amounts while it is higher when the strategy method is employed. In terms of cross-cultural differences, the results of the meta-analysis showed no difference between different geographic regions on the offers of proposers but revealed significant differences in the rejection rate of the responders. Specifically, Asian participants had a higher rejection rate than American participants. Cultural-level differences of individualism and power distance did not predict either sharing or rejection rates.

## Animal Behavior

To understand the evolutionary roots of action strategies such as cooperation, fair-share preferences, and self-interest, researchers look up to the actions of our close relatives: chimpanzees. Recent research showed that chimpanzees and capuchin monkeys display preferences similar to humans in terms of cooperation and aversion to unequal treatment (e.g., Brosnan et al. 2005; Melis et al. 2009). Therefore, how those non-human primate cousins behave in the presence of another agent that has the opportunity to influence the outcome of the action, as in the ultimatum game, attracts the attention of researchers. Recent research on chimpanzees and bonobos revealed that nonhuman primates behaved in line with the expectations of the game-theoretical perspective: They offered the smallest amount possible, and nonhuman primate responders accepted almost every offer even if the offer were zero, implying that they might fail to apprehend the task and hence cannot be evaluated as rational maximizers (Jensen et al. 2007; Kaiser et al. 2012). However, designs of these experiments have been criticized since they utilized a device not present in human experiments: Games were played within

primates' social group which violates anonymity. Besides, the incentive was food instead of a more abstract reward such as money (primates have been shown to provide strong responses to visual food inputs, Boysen and Berntson 1995). Furthermore, unique to the primate version, they reject the offer by inhibiting their actions and waiting for 30 s which have been shown to influence human actions as well. Smith and Spielberg (Smith and Silberberg 2010) replicated the chimpanzee experiment on humans and found that waiting before taking action decreased the rejection rate of the responder from 52% to 18%.

In a more recent experiment, children and chimpanzees were recruited for two tasks similar to the ultimatum game and dictator game (Proctor et al. 2013). They used tokens with a trade value akin to money used in human designs. Chimpanzees were next to each other in two different rooms positioned against six slices of bananas. They had two options, equal share token which is used to trade three slices for each, and unequal share token which is used to trade five slices for the proposer and one slice for the responder. Each chimpanzee took 12 trials, and as a result, in 75% of all trials, they preferred the equal share token. In the same experiment, chimpanzees played another game such as the dictator game in which each chimpanzee is matched with a "foil" partner, naïve to the conditions and passive to the share offered by the proposer. In this version, 90% of the chimpanzees preferred the unequal (selfish) token. Those results were in line with the children sample tested in the same experiment.

Overall, the ultimatum game is a powerful tool to study human and nonhuman primates' social behaviors. Future research should strive to increase the level of comprehension of the ultimatum game, for both human and nonhuman participants.

## Umwelt

Justin A. Varholick  
Department of Biology and UF Genetics Institute,  
University of Florida, Gainesville, FL, USA

## Synonyms

Environmental influences

## Definition

The perceptual-reactive world of an organism. These worlds are manifold and varied – much like the animals themselves. Humans are limited to their own perceptual-reactive worlds, making it difficult to comprehend the worlds of other organisms, especially when some perceptual domains of the organism are not shared with humans. The term was originally coined in the field of ethology by Jakob von Uexküll (1934, 1982).

## A “Simple” Umwelt

A classic perceptual-reactive world that nicely exemplifies the meaning of the Umwelt is that of a tick. Ticks may become part of the human perceptual world when they burrow into our skin, or the skin of our pets, and gorge themselves with warm blood. Thus, our perception of ticks may be one of unpleasantness. They trigger our sense of touch from the burrowing, which then signals the visual system to investigate the source – the perception and then the reaction. The Umwelt of a tick however is quite different and strange from our perception. Ticks are often found clinging to the top of a twig or the tip of a blade of grass, waiting to drop upon small animals or be brushed off by larger ones. They are blind and deaf, but consistently travel to these locations, or stands, by a general photosensitivity on their skin. Once on their stand, ticks use their sense of smell, which includes the chemical sensing capability of detecting the odor of butyric acid secreted by the skin glands of all mammals. They may detect other animals (e.g., lizards) by other chemicals in their breath, body heat, moisture, vibrations, etc. The detection of an animal stimulates the tick to drop from its stand, land on or orient to and locomote to the animal source of the stimulus on the animal, i.e., the skin. Locomotion ends at a hairless spot and this stimulates burrowing into the skin to gorge itself with blood. Importantly, ticks cannot taste; thus, they are unable to detect whether they are consuming blood (a tick will consume any fluid that is comparable to warm blood). If the stimulus of the butyric acid signals

the tick to leave its stand, but causes the tick to land on something cold, it will have missed its prey and antigravity reactions will result in it climbing up to a new stand. However, if the tick does land and feed on a warm-blooded mammal, the blood will be its last meal. Upon gorging itself, the tick will drop to the ground to lay eggs and then die.

As demonstrated from the example of a tick, the perceptual world of an organism is highly dependent on the organism's sensory system, motor system, and nervous system – its perception and reaction. The tick sensed butyric acid, which stimulated its motor system to move off the stand and to drop onto the mammal emanating the chemical. The sensation of butyric acid is just one sense within the modality of chemical sensation. Other common sensory modalities include vibration, body movement, physical contact, electromagnetic, and temperature. These modalities serve as general sensory categories and different animals may perceive different aspects of each sensory modality. For example, ticks can perceive butyric acid but cannot sense – or taste – the chemicals in the blood. Like the sense of butyric acid, other organisms have sensory abilities beyond that of humans, which are often given the ultra- or infra- prefix. For example, snakes, such as pit vipers, pythons, and boa constrictors, can perceive infrared (IR) light through IR-sensitive receptors on their heads (Gracheva et al. 2010). Humans, in contrast, cannot detect this range of light, but can detect the associated heat that is emitting from the object that is also emanating the IR light; any object that is warmer than its environment emits IR radiation. Humans are also unable to detect ultraviolet light, which is perceived by butterflies, bees, and some birds. Because these ranges of light are invisible to the human eye, it is difficult to comprehend the visual world of these animals. Fortunately, technology has made it possible to view both IR and ultraviolet light, thereby expanding our sensory capacity. However, it would be facile to suggest that with these technologies we are fully able to comprehend the Umwelt of dissimilar animals (Dethier 1962, 1969).

## Interpenetration of Organisms and Umwelts

Organisms and their Umwelts are dialectically related, and therefore cannot be separated from one another; there is no organism without an Umwelt and no Umwelt without an organism. This dialectical property means that both the organism and their Umwelt interpenetrate one another in several forms (Lewontin 1982), all which need to be incorporated into any theory concerning organism behavior or cognition.

First, organisms assemble their Umwelts depending on their total morphology, physiology, and behavior. Organisms will actively assemble their Umwelt by manipulating bits and pieces of the ecosystem they reside within. For instance, some bird species assemble their nests with dirt and avoid grass. Others seek crevices in rocks or holes in trees. This limits the type of stimuli the birds will receive and the types of organisms they may interact with. Organisms will also passively assemble their Umwelt as a consequence of their morphology and physiology. For instance, humans produce a warm layer of air around their body by their own metabolic heat. Some small or microscopic organisms (e.g., fleas or ectoparasites) may reside within this warm layer, thereby the Umwelt of the microscopic organism is dependent on the existence of the human within the ecosystem, which the human itself assembled. Thus, the human assembled an Umwelt wherein another organism could reside, thereby allowing the microscopic organism to become part of the Umwelt of the human.

Second, organisms alter their Umwelt by consuming food, depositing waste, constructing homes, and other activities. This allows them to create the conditions necessary for life, but it may also have destructive consequences for their offspring when alterations ultimately change the habitat of the species. For example, beavers will construct dams in rivers to form a small pond as their home. This fundamentally changes the ecology of the area, allowing different vegetation and organisms to live in the pond which could not inhabit the river. Beavers may also be selective in the trees they may use for their dam, because

they only prefer certain species. This further alters the environment, by removing preferred species of trees, sometimes to the extent that it is unsuitable for themselves and their offspring. This behavior is not only limited to wild organisms but can occur in the laboratory. For instance, laboratory mice build their own nests and deposit waste in their home-cages, thereby fundamentally altering their Umwelt daily; nest building alters body temperature and waste modulates olfactory cues in the environment.

Third, organisms transduce physical inputs qualitatively. When an event occurs within an ecosystem, different organisms may not necessarily perceive the event of the same quality. For instance, when a female ring dove is presented with a nest and eggs, it will secrete prolactin. This signal can be modulated, dampened or amplified, across a ring dove's development, wherein a reproductively naive male or female ring doves will not show the same physiological or behavioral response as reproductively experienced doves (Lehrman 1965). Moreover, individual differences exist concerning the secretion of prolactin between ring doves of the same sex and age. Of course, the presence of a nest and eggs may be differentially perceived by a passing snake – albeit different snakes will have different perceptions depending on their satiety and other factors.

Fourth, organisms modulate the signals from their environment statistically. This is similar to the aforementioned example, but also involves integration of other signals. For instance, squirrels will store acorns or nuts for the winter through behavioral mechanisms in response to fluctuations in food availability. They may also indirectly store energy in the form of body fat or glycogen. Thus, they can modulate, or dampen, the signals of low food supply. Thus, all sensory systems have a “volume-control” feedback circuit that can be adjusted to modulate how a signal will be perceived by the organism.

Taken together, the Umwelt is quite complex and easily misunderstood. Without acknowledging their Umwelt, we may be misinterpreting what the animals are perceiving and what factors are affecting their actions. As scientists, we may add items to an organism's environment to study

them, but the organisms might not respond in the expected manner if the item is not transduced as we intended (Lahti 2015). Moreover, the environment we provide for an animal may be differentially altered across time or by each organism within the environment. Such alterations may render the environment as physically different from what the scientist intended, thereby altering the types of stimuli the organism will perceive and react to. It is imperative for scientists to recognize these Umwelts whenever studying their respective animals, particularly those which diverge in their sensory abilities and capacities from ours.

## Uncertainty Paradigm

J. David Smith<sup>1</sup>, Barbara A. Church<sup>1</sup>,  
Michael J. Beran<sup>1</sup>, J. Antonio Salamanca<sup>3</sup> and  
David A. Washburn<sup>2,3</sup>

<sup>1</sup>Department of Psychology, Language Research

<sup>3</sup>Georgia State University, Atlanta, GA, USA

Humans have feelings of uncertainty and confidence, of not knowing and knowing. They respond appropriately to these feelings by reflecting, rethinking, and seeking additional information. These responses ground the human literature on uncertainty monitoring and metacognition (Dunlosky and Bjork 2008; Flavell 1979; Koriat 1993; Nelson 1992). Humans' uncertainty awareness reveals a high-level cognitive capacity in them that is allied to their conscious awareness. Thus, it was a natural question whether nonhuman animals (hereafter, animals) might share with humans some aspects of a metacognitive capacity (Smith 2009; Terrace and Metcalfe 2005), because the answer to that question could bear on animals' consciousness and self-awareness, too.

Given the question's importance, Smith and his colleagues inaugurated a new area of comparative inquiry by asking whether animals have a capacity for uncertainty monitoring and metacognition regulation. The key to opening up this research area was to address directly difficult methodological issues. Clearly, one cannot just test animals in human paradigms, asking them about their feelings of knowing and their tip of the tongue states. The production of such declarations is presently not practical, though perhaps not in principle out of the question in the future. So investigators faced the problem of letting animals make purely nonverbal, behavioral responses that might

nonetheless serve as valid indicators of their judgments of uncertainty and confidence. Thus was born the uncertainty paradigm (Shields et al. 1997; Smith et al. 1995, 1997, 1998, 2003).

The paradigm had two key elements. First, the tasks contained an important subset of trials that were known to be difficult for the subject. The purpose of these trials was to foster states of doubt and uncertainty in animal minds. Second, animals were given an additional response in the task – outside the primary grammar of the operant-discrimination task – with which animals could freely decline to complete any trials they chose. This uncertainty response (UR) allowed animals to “declare” their uncertainty behaviorally and, crucially, observably. If animals can monitor internal states of certainty and doubt, then they would ideally decline the most difficult trials in a task that are likely to produce errors and delay reward.

The uncertainty paradigm that was created for animals turned out to have deep intellectual roots. In human psychophysics, early experimental subjects were sometimes allowed to respond “uncertain” or “equal” when they felt unable to classify a stimulus (Angell 1907; Fernberger 1930; George 1917; Watson et al. 1973). Some researchers even hypothesized that the UR was psychologically distinctive from the task's primary perceptual responses, in particular a higher-level or metacognitive overarching judgment. In this, they foreshadowed the debate about the appropriate interpretation of animals' URs. For if URs have this status for animal subjects, too, the theoretical implications would be very important.

The uncertainty paradigm also found a strong resonance with explorations of animal consciousness. For instance, Weiskrantz (1986, 1997) was keenly interested in studying animal consciousness purely behaviorally. In an influential thought experiment, he considered giving animals both primary discrimination responses and also a commentary response so that they could report on the state of their knowing or perceiving. Of course, the uncertainty paradigm essentially gave animals this commentary response.

Smith et al.'s (1995) first application of the uncertainty paradigm tested a bottle-nosed

dolphin (*Tursiops truncatus*). In an auditory threshold task, the dolphin discriminated high tones (half the trials, always 2100 Hz, high response) from low tones (half the trials, 1200–2099 Hz, low response). But he could also respond uncertain to decline to complete any trials he chose and receive an easy following trial instead.

Figure 1a shows that the dolphin made high responses and low responses, respectively, for many high trials and low trials. But he also evaluated correctly when he was “at sea” within the discrimination, and he selectively declined to complete those threshold trials. Remarkably, his URs were most frequent near 2.0856 Hz, 1/9th of a half step from the 2100 high tone. No one, not even Yo Yo Ma, could ever resolve that pitch contrast. The fact that the UR was used most at the dolphin’s true perceptual limit must affect one’s theoretical interpretation of that response, because, by definition, there was no discrete pitch

class discernible there that could have prompted some conditioned response.

An additional result (Fig. 1b) was that the dolphin showed his own uncertainty behaviors on threshold trials: he hesitated, swam slowly, waggled his head, and worked his mouth. Through this result, the uncertainty paradigm found important historical resonance again – now with the work of Tolman. Tolman also observed behaviors of this kind that he called “lookings and runnings back and forth” and that he thought could be considered as “a behaviorist’s definition of consciousness” (Tolman 1927, 1938).

Smith, Washburn, and colleagues quickly followed up this dolphin study with research on the joystick-trained macaques (*Macaca mulatta*) at the *Language Research Center* of *Georgia State University* (Smith et al. 1997). Macaques discriminated unframed boxes on their computer screens that were either sparse or dense in lit

# **Uncertainty Paradigm,**

**Fig. 1** (a) A dolphin’s auditory-threshold performance in the uncertainty paradigm used by Smith et al. (1995). Response percentages are plotted against the frequency (Hz) of the trial. For 2100 Hz trials, the high response was correct. The low response was correct for all tones below 2100 Hz. The percentages of high and low responses are shown. The bold line shows the percentage of uncertainty responses made at each pitch level. (b) The dolphin’s composite hesitation-wavering behavior for tones of different frequencies. **Uncertainty Paradigm, Fig. 2** The screen from a trial in a sparse-uncertain-dense discrimination (Adapted from Smith et al. (1997). Copyright 1997 by Elsevier. Reprinted with permission.)

pixels. They used a joystick to move a cursor to touch a box, an S, or a star (Fig. 2). Touching the box or the S was appropriate as the box was dense (half the trials, always 2950 lit pixels, dense response) or sparse (half the trials, 450–2949 lit pixels, sparse response). Moving the cursor to the star allowed the monkeys to wave off the current trial and move on into a new, easy trial instead.

Figure 3a shows that monkeys made dense and sparse responses appropriately. But they also assessed accurately when they were liable to err and they fended off those threshold trials. That is, they made URs (star responses) most in the zone of maximal difficulty wherein their discriminative capacity faltered and they could not reliably tell sparse from dense. This area surrounds the crossing point of the monkeys' dense and sparse response curves, their exact sparse-dense indifference point. Remarkably, humans produced the identical result in parallel studies (Fig. 3b). In addition, humans told us that they used the UR when they consciously knew they did not know or could not tell the trial's status. Of course, if animals' URs express animals' conscious metacognition in the same way, then they are profoundly important behavioral expressions of animal awareness.

But wait. What were the dolphins and monkeys thinking in their tasks, or what were they merely

reacting to? Were they self-reflecting on uncertain mental states? Or were they simply averse to the objective perceptual stimuli that signaled difficulty, loss, error, and reduced rewards. The problem is that the original uncertainty paradigm did present objective stimuli for response. Moreover, some of these stimuli were inherently correlated with trial difficulty and reduced reward probability. Thus, the early instantiations of the uncertainty paradigm came in for their fair share of sharp criticism. In fact, a 20-year associative-metacognitive explicit debate ensued about the appropriate low-level (associative) or high-level (metacognitive) interpretation of animals' URs (e.g., Basile and Hampton 2014; Carruthers 2008; Hampton 2009; Jozefowicz et al. 2009; Le Pelley 2012, 2014; Smith 2009; Smith et al. 2008, 2009, 2012a, b, 2014a, b; Staddon et al. 2007). Essentially, this debate organized the entire early development of this research area.

During this debate, many variants on the original uncertainty paradigm were developed. An especially influential example came from Hampton (2001) who brought the uncertainty paradigm into the domain of memory (also see Kornell et al. 2007; Smith et al. 1998). In Hampton's study, macaques performed a delayed matching-to-sample task. On some trials, following the disappearance of the sample and the delay (forgetting interval), monkeys had the choice to either complete the memory test – possibly gaining a preferred reward – or to decline the memory test – settling for a lesser reward. On other trials, macaques did not have the UR option available and were required to complete the memory test. Figure 4a shows Hampton's principal results. He reported that macaques made URs more often after longer forgetting delays, naturally so because their trial memory was fading. But Hampton also reported that, when macaques eschewed the UR and chose to complete the memory test, they were quite accurate even at long delays. This suggests that they were in touch with some useful internal signal of remembering that predicted successful matching. This possibility is strengthened by this aspect of Hampton's design; unlike in the early perceptual versions of the uncertainty paradigm, there was no memory

**Uncertainty Paradigm, Fig. 3** (a) A monkey's performance in the uncertainty paradigm used by Smith et al. (1997). The horizontal axis indicates the density of the trial. For 2950-pixel trials – those trials plotted to the far right of each curve – the dense response was correct. For all trials with lesser densities/fewer pixels, the sparse response was correct. The percentages of dense and sparse responses are shown (dashed lines). The percentage of trials receiving

the uncertainty response at each trial level are shown in the solid line. (b) The performance of humans in the sparse-uncertain-dense discrimination depicted similarly. To align the different sparse-dense thresholds of different humans, the data were normalized so that each participant's discrimination threshold fell at about 2700 pixels. (Adapted from Smith et al. (2003). Copyright 2003 by the Cambridge University Press. Reprinted with permission.)

**Uncertainty Paradigm, Fig. 4** (a) A macaque's performance in the uncertainty paradigm used by Hampton (2001). The horizontal axis indicates the length of the retention interval before matching could occur. The percentages correct are shown for memory tests completed when the memory test was required (dashed line) or optional and intentionally chosen by the macaque (dotted line). The percentage of trials receiving the uncertainty

response is shown in the solid line. (Adapted from Hampton (2001). Copyright 2001 by The National Academy of Sciences.) (b) Pigeons' performance in the similar uncertainty paradigm adopted by Inman and Shettleworth (1999). (Data graphed with permission from Inman and Shettleworth (1999). Copyright 1999 by American Psychological Association.)

relevant material visible and no concrete stimulus present to avoid or escape. In this case, the uncertainty paradigm demonstrated that it can transcend low-level, associative processes, and target rather

high-level memory processes approaching humans' capacity for metamemory.

Templer and Hampton (2012) presented additional experiments that reinforced this conclusion,

and Basile et al. (Basile et al. 2015) presented systematic research evaluating seven potential associative explanations of macaques' URs in memory tasks. They found (p. 85) no support for the "hypotheses of behavioral cue association, rote response learning, expectancy violation, response competition, generalized search strategy, or postural mediation." But they repeatedly found results supporting the memory-monitoring hypothesis. They concluded (p. 85) that monkeys "can use memory strength as a discriminative cue for information seeking, consistent with introspective monitoring of explicit memory."

The uncertainty paradigm has also fulfilled its theoretical and empirical promise by sharply contrasting the cognitive-monitoring capabilities of different vertebrate lines. For example, Inman and Shettleworth (1999) evaluated pigeons' meta-memory capacity using an approach like that in Hampton (2001). Pigeons given longer forgetting intervals showed only a 7% increase in URs (Fig. 4b). This increase was not significant using parametric statistics. Moreover, this small increase poorly reflected the birds' poor performance at longer delays, for they *were* forgetting the samples and they could appropriately have used the UR more frequently. Finally, pigeons did not show a meaningful performance improvement when they voluntarily chose to complete the matching trial compared to when they were required to complete it. This suggests that they were not monitoring any felicitous internal signal of "still remembering" as the macaques apparently did. All in all, comparing Fig. 4a, b, one sees that there is distinctive difference between the metacognitive data pattern that macaques showed and the alternative pattern that pigeons showed.

Sutton and Shettleworth (2008) replicated these pigeon findings using converging experimental methods across several experiments. Pigeons still did not choose to make URs at levels corresponding to their decreases in matching accuracy. In short, all the pigeon applications of the uncertainty paradigm show very different results from those found with macaques in equivalent procedures. Sara Shettleworth and her colleagues deserve great credit for so thoroughly

applying the uncertainty paradigm to the matching performance of pigeons – even if the empirical answer is essentially that pigeons do not easily express an uncertainty-monitoring capacity. In this case, a strong comparative No may be the theoretically clearest and strongest and most interesting answer of all.

The pigeon research is a strong confirmation that the uncertainty paradigm is able to make sharp differentiations among the uncertainty monitoring abilities of different species. This research is also a rebuke to the idea that URs are only another associative response. If they were, pigeons would make URs easily just as they make easily many other associative responses. But macaques adaptively make appropriate URs, pigeons do not easily do so (Adams and Santi 2011), suggesting that the uncertainty paradigm can also sharply differentiate responses of different psychological characters and possibly at different levels in the cognitive system.

The uncertainty paradigm has even been used to reveal important species differences in uncertainty monitoring within the order *Primates*. For example, Beran et al. (2009) used the paradigm to test the uncertainty-monitoring capability of capuchin monkeys (*Cebus apella*, a New World monkey species). They gave six capuchins two closely related tasks of density discrimination. The first task was the sparse-uncertain-dense task, an application of the uncertainty paradigm that has been described. This task had difficult trials surrounding the breakpoint between the sparse and dense stimulus regions along the density continuum. Monkeys had available the UR by which they could decline selected trials. So, this task let monkeys declare – in a sense – that they didn't know if that trial was sparse or dense. The second task was a similar sparse-middle-dense task. This task let monkeys be directly rewarded for making a middle response to stimuli in the midrange of the continuum. So, this task let monkeys affirmatively and concretely declare – in a sense – that was a middle trial.

Figure 5a shows that in the first task capuchin monkeys hardly made any URs. This result can be compared to the result shown in Fig. 3a wherein macaques made URs frequently and adaptively to

**Uncertainty Paradigm, Fig. 5** (a) Capuchin monkeys' performance in the sparse-uncertain-dense task used by Beran et al. (2009). The horizontal axis indicates the density level of the box. The sparse and dense responses, respectively, were correct for boxes at density levels 1–21 and 22–42. The solid line represents the percentage of trials receiving uncertainty responses at each trial level. The

percentages of trials ending with the sparse response or dense response are also shown. (b) The performance of the same capuchin monkeys in the sparse-middle-dense task depicted similarly. (Adapted with permission from Beran et al. (2009). Copyright 2009 by the American Psychological Association.)

decline the range of difficult, error-causing trials. However, Fig. 5b shows that in the second task, capuchin monkeys used the middle response fluently.

To possibly foster capuchin monkeys' URs by increasing that response's value, Beran et al. (2009) increased the penalty timeout for an error from 20 s to 90 s. Now, the cost of error was high – animals could potentially complete 30 trials correctly to gain 30 food rewards during the timeout brought by one error. Yet despite having now a much stronger motivation for URs, they still hardly used that response.

Through this experiment's uncertain-middle dissociation, the uncertainty paradigm showed again its ability to differentiate responses that have different psychological characters. Probably, the middle response is associatively bound by reinforcement to a class of middle discriminative stimuli. Capuchin monkeys used this response fluently. They clearly responded to the signal from the middle stimuli and responded to them to maximize their task rewards. If URs were associatively bound to the same middle stimulus range in the same way, as associative theorists have suggested, capuchin monkeys would have made

that response fluently as well. But they did not. They barely monitored the uncertainty paradigm's uncertainty signal, and they seemed not to respond to that signal to maximize reward. Thus, the uncertainty paradigm – through its uncertainty response – taps into a different psychological mechanism than does the sparse-middle-dense task with its middle response. In this study, one sees clearly the three empirical/theoretical themes that define the essence of the uncertainty paradigm. First, it clearly differentiates the uncertainty-management systems of different species – in this case, capuchin monkeys and rhesus macaques. It is an exciting aspect of this area that these cross-species comparisons continue to expand (e.g., Foote and Crystal 2007, 2012; Suda-King et al. 2013; Templer et al. 2017). Second, it clearly differentiates responses of different psychological levels – in this case, an associative (middle) response bound behaviorally to stimuli through concrete rewards, and a decisional (uncertainty) response that reveals a higher-level cognitive capacity that could have emerging ties and similarities to humans' metacognitive capacity. Third, the uncertainty paradigm insistently requires that comparative psychology's tendency

to assume a unitary, associative system as the governor of animals' behavior must be questioned. It is time to elaborate our theories of animal minds in ways that will foster the careful study of animals' higher-level cognitive processes.

However, the precise information-processing structure of this higher-level cognitive capacity remains to be illuminated. That work of illumination is occurring presently in the literature. For example, Smith et al. (2013) confirmed that the uncertainty response in the uncertainty paradigm is psychologically distinctive for drawing especially heavily on working-memory resources. They placed macaques in the sparse-uncertain-dense task that was already described. Once again, the UR let monkeys decline difficult trials near their discrimination thresholds as well as any other trials of their choosing. However, now Smith et al. added a secondary task requirement to the ongoing discrimination, so that monkeys needed to actively maintain memory material while performing their sparse-uncertain-dense trials. The secondary task acted as a concurrent

cognitive load, and it was possible to then examine the effect of the memory load on the use of the various responses in the task.

The experiments considered how the concurrent memory load might affect perceptual-classification processes as compared to the processes that support uncertainty monitoring and URs. Smith et al. suggested that the uncertainty paradigm's primary perceptual responses might be more stimulus-based, reactive, and associative, making few demands on working memory or executive attention. In that case, sparse and dense responses would hardly be affected by the memory load. In contrast, Smith et al. evaluated the possibility that URs might be severely affected by the memory load – if they are a higher-level response that needs the resources of working memory.

Figure 6 shows the article's main results. The concurrent load in essence did not affect macaques' sparse and dense responses at all. In sharp contrast, the load disrupted macaques' URs severely. This result strongly urges that the UR in the uncertainty paradigm not be considered as

**Uncertainty Paradigm, Fig. 6** Macaques' performance in the uncertainty paradigm used by Smith et al. (2013). (a) Performance is shown in a baseline condition to illustrate uncertainty responding under control conditions. The percentages of sparse and dense responses are shown (dashed and dotted lines, respectively). The percentage of uncertainty responses made at each trial level are shown in the

solid line. (b) Performance is depicted in the same way for the concurrent-load condition to illustrate uncertainty responding when monkeys were given a concurrent working-memory load. (Adapted with permission from Smith et al. (2013). Copyright 2013 by the American Psychological Association.)

equivalent to the primary perceptual responses. Instead, it clearly seems to reflect higher-level cognitive processing that may depend especially strongly on the active use of working-memory resources.

In fact, in an additional dissociation, Smith et al. (2013) found that middle responses in a sparse-middle-dense discrimination, like sparse and dense perceptual responses in a sparse-uncertain-dense discrimination, were minimally affected by a concurrent memory load. Coutinho et al. (2015) showed that this is also true of humans performing with working-memory interference. So, Smith et al. (2013) also produced an uncertain-middle dissociation. The robustness of the middle response is explainable because it mapped to an objective range of stimulus levels (interestingly, the same concrete stimulus levels to which the uncertainty response mapped). Middle responses to those stimuli were immediately rewarded, clearly creating ideal conditions for the processes of associative learning. This dissociation supports the idea that the primary perceptual responses included in the uncertainty paradigm – in this case, sparse, dense, and middle responses – result from the operation of something like associative-learning processes. But the uncertainty response apparently does not. One sees that these results have a strong theoretical resonance with the uncertain-middle dissociation shown in capuchins by Beran et al. (2009).

The problem for associative accounts of the uncertainty paradigm is that they have assumed a theoretical equivalence between the UR and the task's perceptual responses. They do not allow that these response types might be qualitatively different for having different requirements in resources and requiring commitments from different levels in the cognitive system. But the response types do seem to have these different requirements and different cognitive levels. Therefore, to lump them together – under the label associative responding – is theoretically inadequate because it blurs the most important theoretical distinctions. But if one assumes that the UR is a higher-level, decisional response that is particularly dependent on working memory and attentional resources, this is theoretically adequate

for describing this result. It is also consistent with the theoretical possibility that the UR within the uncertainty paradigm is an elemental behavioral index of uncertainty monitoring.

Finally, Paul et al. (2015) provided one capstone finding that places the uncertainty paradigm within a neuroscience framework while also clearly justifying the UR as a distinctive psychological element in a cognitive task above and beyond the primary responses within the task grammar. They gave humans the sparse-uncertain-dense task that has already been described. The sparse-to-dense continuum was equally divided into sparse and dense regions that deserved the sparse and dense response, respectively. The task's discrimination breakpoint lay at the continuum's center and naturally the most difficult and uncertain trials in the task surrounded this sparse-dense breakpoint. Then, Paul et al. used rapid event-related fMRI to show the neural-activity patterns that underlay humans' uncertainty responses and their perceptual responses (sparse, dense). The findings showed that the activity patterns for the two response types were distinctively different.

Figure 7 (top) shows the simple neural-activation pattern found when participants made correct sparse or dense responses instead of choosing the uncertainty responses. There was activation in the occipital lobe bilaterally and in the caudate and nucleus accumbens. This pattern expresses well the theoretical idea that sparse and dense responses are first-order responses to concrete perceptual events that produce well-associated behaviors.

In contrast, Fig. 7 (bottom) shows the complex neural-activation pattern when participants made uncertainty responses instead of sparse or dense responses. Uncertainty responding activated a distributed network including prefrontal cortex, anterior and posterior cingulate cortex, anterior insula, and posterior parietal areas. Thus, uncertainty monitoring apparently benefits from a widespread network for controlled cognition that includes recently evolved brain regions such as the anterior dorsolateral and medial prefrontal cortex. If URs were just associative responses, as some have argued, they would not need to activate

**Uncertainty Paradigm,  
Fig. 7** Humans'

performance in an uncertainty paradigm depicted from an fMRI perspective. *Top.* Whole-brain results from the contrast correct sparse-dense response > uncertainty response projected on an inflated lateral and medial cortical surface. Table 2 in Paul et al. (2015) gave the coordinates and voxel numbers for significant clusters. Images were cluster thresholded (correcting for multiple comparisons) at  $z > 3.54$ ,  $p < .01$ . *Bottom.* Whole-brain results from the contrast uncertainty response > correct sparse-dense response projected on an inflated lateral and medial cortical surface. Table 3 in Paul et al. (2015) gave the coordinates and voxel numbers for significant clusters. Images were cluster thresholded (correcting for multiple comparisons) at  $z > 3.54$ ,  $p < .01$ . this complex neural network. Instead, one is led to conclude that URs are quite psychologically distinctive and do involve higher-level judgments of difficulty, prospects, or mental states of knowing. Clearly, the neural circuit involved in adjudicating task uncertainty is far different from, and more complex than, the circuit involved in settling on one of the two primary perceptual responses.

Of course, this human experiment throws down a gauntlet to animal researchers that at some point they will need to take up with new brain-imaging approaches. And yet this result clearly suggests strongly that the uncertainty

paradigm is tapping into something extremely important about human and animal minds. This result recalls Tolman's sense that URs could be the behaviorist's definition of consciousness. It recalls psychophysicists' idea that URs are less perceptual, more psychologically complex. It recalls Weiskrantz's idea that URs amount essentially to a commentary key by which animals may declare their knowing or not knowing, their certainty or uncertainty. Thus, for many reasons, the uncertainty paradigm in animal-metacognition research has proved to be an influential, theoretically challenging resource for many researchers

and the source of scores of intriguing investigations of cognition across species. Indeed, quite possibly, the uncertainty paradigm lays important groundwork for future research paradigms that may positively identify animal consciousness and awareness.

The uncertainty paradigm has also become part of the ongoing discussion about animal care and husbandry, and animal rights. Given that many animals evidently monitor their uncertainty and their doubts, their states of remembering and not knowing, it becomes highly plausible that they monitor other aspects of their mental experience as well. And thus, the uncertainty paradigm, by systematically elevating comparative psychology's view of animals' minds, insistently also elevates the level of care and respect that is owed to those animal minds and animal lives.

## Unconditioned Response

D. A. Williams  
University of Winnipeg, Winnipeg, MB, Canada

### Synonyms

[Modal action pattern](#); [Reflex](#)

### Definition

*Unconditioned responses* are evoked by the first presentation of a stimulus.

### Introduction

*Unconditioned responses* (URs) are unlearned species-specific responses. Salivation was the UR evoked by a number of substances placed in the mouth of dogs by Pavlov (1927) and his students, including wet food, dry food, weak acid, and sand. Inedible substances, like sand, would evoke salivation only when placed in the dog's mouth. The visual appearance of sand did not evoke salivation until the dog had learned the unfortunate destination of this substance was its

mouth (Todes 1997). It appears that placement of practically any substance in the dog's mouth produced a salivary unconditioned response.

On the other hand, the dog's reaction to the visual appearance of various foods was probably learned through association before the dog was captured on the streets of Saint Petersburg, Russia. Edible substances evoked salivation upon sight and contained larger amounts of mucin. Previous experience had presumably already installed an association between the conditioned stimulus (CS, sight of food) and the food unconditioned stimulus (US). In a similar way, a pigeon will learn to peck at an illuminated disk on the chamber wall when it is differentially associated with food (Gamzu and Williams 1971). Pecking is a conditioned response (CR). It is not the product of instrumental reinforcement because the pecking response has absolutely no effect on the probability of food.

Unconditioned responses span the range from very simple reflexes (sensory nerve → interneuron → motor nerve) to quite complex behavior patterns. An animal attacked by a predator feels pain (an emotion), it jumps, flinches, and vocalizes (skeletal responses), and experiences high levels of arousal (sympathetic nervous system). Moving toward appetitive stimuli (approach) and retreating from aversive stimuli (withdrawal) are sometimes URs and sometimes CRs, depending on the organism. Orienting responses bring animals' sensory organs in a better position to process stimuli in the environment. Taste reactivity tests assess the oral and facial reactions of babies and rats to sweet and sour substances to discern the hedonic value (liking) of rewards (Berridge 2000).

### Sensitization and Habituation

The magnitude or probability of unconditioned responses may increase or decrease, depending on a large number of factors. Habituation is defined as a response decrement that results from repeated stimulation and that cannot be due to sensory adaptation, sensory fatigue, or motor fatigue. Habituation can be either short-lived or

long-lived, and the factors that cause short-term effects are not the same as those causing them to stick for the long term. Consider the startle response. Rats' startle when they hear a loud sound, and this response diminishes more quickly over trials (repeated presentations) if the sound is repeated every 2-s than every 16-s. Although short intervals encourage faster and deeper habituation during stimulus presentations, the retention of habituation at a later time is uniformly better after a 16-s training interval than a 2-s training interval (Davis 1970). The effects of intertrial interval are very common across species and situations, causing Thompson and Spencer (1966) to add this factor to a list of eight other behavioral characteristics of habituation.

Sudden or threatening events, such as loud noises or sharp taps on the shoulders, also cause people to startle. Jaws clench (we wince), eye muscles close (we blink), shoulders jerk upward, and even our legs move. Emotional states evoked in people viewing positive, neutral, or negative pictures modulate the degree of startle. Negative pictures enhance the eyeblink startle response, and positive pictures reduce it (Vrana et al. 1988). Fear-potentiated startle is well studied in both humans and animals because of its potential relevance for understanding post-traumatic stress disorder. That sensitization rather than habituation of responding is a possibility led Groves and Thompson (1970) to suggest the existence of both a decremental process (habituation) and an incremental (sensitization) process which interact over trials to determine the behavioral outcome.

Studies of the relatively simple organism, *Aplysia californica*, by the Nobel Laureate Eric Kandel (2001) have uncovered exactly how these two hypothesized processes can operate at the neural level. His laboratory identified which of just 20,000 large, easily identified neurons produce sensitization and habituation of the gill-withdrawal response. Subsequent research found the neurotransmitter serotonin was a key player in the sensitization of the response and identified some of the proteins that had to be synthesized to convert short-term changes in synaptic transmission into long-lasting memories.

## Opponent Process Theory

Some unconditioned stimuli evoke bidirectional changes. An initial reaction is followed by any secondary reaction, which serves to bring the organism back into a *homeostatic* balance. Solomon and Corbit (1974) argued that emotional responses are especially prone to this dynamic pattern of activity. Frightening events evoke intense fear, followed by adaption and thereafter by feelings of relief when the danger has ceased. Some psychoactive drugs produce euphoria, followed by adaption, and finally anhedonia when drug is eliminated from the body. Solomon and Corbit hypothesized that manifest affective reactions in these situations are controlled by two opposing forces: (a) an a-process triggered by the presence of the event that remains unabated during the entire duration of the event and (b) an opponent b-process of the opposite emotional quality aroused by the a-process to provide a homeostatic limit. On the first trial, the sluggish onset and inherent weakness of the b-process explains the long delay for adaptation to materialize, and the lingering effects of the b-process explain why a modest counter-reaction is observed after the event is withdrawn. As the event is repeated, the b-process grows in immediacy and strength, leading to habituation and a more intense counter-reaction.

The parallels between these changes to drug tolerance and withdrawal should be readily apparent. Counter-reactive processes sometimes fail to return the person to within the normal level in after drug taking has ceased altogether. When this occurs, neuroadaptive mechanisms return the person to a new *allostatic* state, making them vulnerable to relapse.

## Facilitation and Diminution of the UR

Signaling the US can lead to either facilitation or diminution of the UR. If the CR and the UR are complementary, such as found in the studies of the salivation in dogs (Pavlov 1927), the combined effects of anticipatory salivation evoked by the CS

and unconditioned salivation elicited by the US might be additive. However, the more likely result is diminution of the UR. This may occur for two reasons. First, the CR may enter into association with b-process rather than the a-process, leading to a compensatory CRs. Contexts associated with painful shocks support conditioned hypoalgesia (reduced pain) by virtue of the existence of anti-pain mechanisms in the brain. Second, the prediction of the US may reduce surprise value of the US. Even when the CR and UR take the same form, signaling the US can diminish the UR. As the intensity of the US is increased in eyelid conditioning in the rabbit, the UR switches from being higher on CS+US trials than US alone trials to the opposite (Donegan and Wagner 1987).

## Conclusion

*Unconditioned responses* (URs) are unlearned, but they are certainly not unchangeable or static. They may sensitize or habituate over repeated trials and can be facilitated or diminished by signaling with a CS or context. Secondary URs can be conditioned leading to compensatory CRs.

## Unconditioned Stimulus

D. A. Williams

University of Winnipeg, Winnipeg, MB, Canada

## Synonyms

[Eliciting stimulus](#)

## Definition

*Unconditioned stimuli* are biologically important events that evoke unlearned responses upon their first presentation.

## Introduction

The term unconditioned stimulus (US) comes from Arnrep's English translation of *Conditioned Reflexes* (Pavlov 1927). It refers to a stimulus falling upon a sensory receptor, either internal or external, that gives rise to a definite response. Pavlov gives the example of making a food (US) available to a hungry animal. The animal is attracted towards the food and consumes it, the unconditioned reflex (UR). He viewed the UR as an inborn set of well-coordinated responses to the US, which had evolved because of their importance for survival and reproduction. Conditioned stimuli (CSs) also evoked well-coordinated responses, such as investigatory reflexes, but these CSs are vital for survival only to the extent they come to signal the later occurrence of more important USs. CS-US pairings lead to the development of conditioned responses (CRs).

For Pavlov, the difference between CSs and USs was a matter of the motivational value of the stimulus, potential signal (CS), or biologically relevant stimulus (US). It follows from this perspective that biological relevance and not temporal order is the key. During Pavlov's *backward* conditioning procedure, the delivery of the food US preceded the presentation of CS. Pavlov did not re-label the food as a CS just because it came first. This arrangement is only somewhat effective for establishing a conditioned response (CR) compared to the forward CS-US arrangement.

Given the definition of the US as a biologically potent stimulus, the term could be applied in circumstances outside of the Pavlovian conditioning situation. For example, species-specific modal action patterns are released by the occurrence of appropriate stimuli, such as the pecking response of chicks directed to beak-like stimuli (Tinbergen and Perdeck 1950). Although they are more likely to be called eliciting stimuli this instance, it should be apparent these beak-like stimuli are USs by another name. Reinforcers in operant conditioning are also USs in a sense; however, most researchers think it worthwhile to label these stimuli in other terms because their presentation or removal is contingent on the animal making a particular response.

A surprising array of USs has been used in conditioning experiments. Female copulation partners have been employed as USs in studies with domesticated quail, producing a variety of anticipatory CRs in their male partners. Interoceptive stimuli can serve as USs. Initial panic attacks coming "out of the blue" in panic disordered patients may become associated with other normally benign interoceptive sensations (Bouton et al. 2001). These formerly benign feelings may serve as CSs and evoke anxiety and fear, and precipitate a new panic attack. Opiate drugs are powerful USs, producing a wide variety of effects including pain relief, euphoria, and respiratory depression. Compensatory CRs evoked by stimuli uniquely associated with drug delivery are responsible for some of withdrawal symptoms addicts' experience after ceasing use of the drug (Siegel 2001). Overdose is more likely without these compensatory CRs.

## Sensory and Motivational and Components of the US

Konorski (1967) is usually credited with the idea that the CS may enter into separate associations with different components of the US. According to Konorski, the US is a multidimensional stimulus with (a) specific sensory qualities and (b) either appetitive (pleasant/rewarding) or aversive (unpleasant/punishing) motivational qualities. The motivational value of appetitive USs is typically highly variable, regulated by the current needs of the organism. Pre-feeding (satiation) can markedly reduce the value of a particular food, but its texture (one of its sensory qualities) is not affected by changes in the state of the animal. Selective satiation studies examine whether declining satisfaction is generated by the consumption of certain type of foods. They suggest such differences are not limited to general motivational states, appetitive and aversive, but can be far more specific.

The motivational value of aversive USs is less easily manipulated by changing the state of the animal. Motivational value is determined more by the degree of threat (intensity). Life threatening dangers challenge an animals' evolutionary

fitness, and so it makes sense the motivational value of aversive US is less likely to be determined by the animal's current needs. Consider the loud clang US used in Watson and Raynor's (1920) famous study of the fear conditioning of "Little Albert." The aversive internal state evoked by the clang became associated with the appearance of a white rat, the CS, leading to the development of a conditioned fear. There was no need to motivate "Little Albert" with some pre-experimental manipulation.

## US Revaluation

Studies of US revaluation take advantage of the fact that the motivational properties of the US are not fixed. They permit experimental research to determine the nature of association formation, stimulus to stimulus (S-S) or stimulus to response (S-R). Following successful conditioning, for example, the attractiveness of an appetitive US might be changed by satiation (feeding). With the motivational properties of the US diminished at test, we might expect the CR evoked by the CS to also diminish, provided that anticipation of the US (triggered by the CS) is the driving force behind the CR (CS-US or S-S learning). If, instead, the CS were to directly evoke the CR (CS-CR or S-R learning), it follows that the CR should be largely unchanged from the last conditioning trial. Studies of US revaluation have revealed CS-US associations in a variety of different Pavlovian conditioning situations.

Aversive USs are typically revalued by changing their intensity. During conditioning, a tone CS might be repeatedly paired with a moderate intensity footshock US (e.g., 0.8 mA) until a fear CR is observed. During revaluation, the animal might receive a few US-alone trials with a very intense footshock (e.g., 3.0 mA) as a US inflation treatment. It is critical that the US is inflated in the absence of the CS and in a completely different location than in the conditioning or testing box. Otherwise, the results could be attributed to a direct experience with the CS and revalued US or to additional conditioning of situational cues and the revalued US. During testing, the CS is

assessed to determine if it evokes a bigger CR than it would otherwise in non-revalued control group.

## US-US Learning

If USs are spaced at regular intervals, each US may serve as a signal for the next US. This type of learning was first uncovered in Pavlov's laboratory in an experiment conducted by Dr. Feokritova. A dog received pairings of the sound of a metronome with food every 30 min. Time since the last US acted as a cue as shown by the fact the CS evoked the CR if it was tested at the 29th min but not the 5th min.

## Surprisingness of the US

The ability of a US to support further conditioning seems to depend on whether it is fully predicted. Learning curves are generally negatively accelerated with the greatest increases in the CR occurring earlier and smaller increases afterward until asymptote is reached. The CS ceases to gain strength when the US is fully predicted. This suggests that learning is driven by an error reduction process in which the subject's expectations gradually come into line with the intensity of the US. Kamin's (1968) discovery that conditioning could be *blocked* led many researchers to embrace US processing as the primary determinant of conditioning. When a new CS joins an already well-conditioned CS, and the two CSs are together followed by the US, the new CS may display very little ability to evoke the CR when tested in isolation. Rescorla and Wagner (1972) famously hypothesized that all available signals (CSs) contribute to a common prediction of the US, and learning depends on the surprisingness of the US received.

Context blocking is one of the causes of the *US preexposure effect* (Randich 1981). Repeated presentations of the US alone before CS-US pairings interferes with acquisition of the CR. If US alone trials are given in the same apparatus (context) as the subsequent CS-US pairings, the context may

enter into association with the US and reduce the rate of conditioning. Although some have questioned whether blocking is a reflection of a learning deficit (Blaisdell et al. 1999), prediction error signals have been identified in many brain regions and experimental paradigms (Den Ouden et al. 2012), making the account seem secure.

## Conclusion

A wide variety of biologically important events have been used as USs in conditioning, including food, footshock, sexual partners, and drugs. USs are multifaceted events with motivational properties (which make it a US) and sensory/perceptual properties (which allow it to act as a signal for another US). Errors in predicting the arrival of the US drive association formation to reduce surprise.

## Ungulate

Nadia Miecznikowski and Sarah Snider  
Zoo Atlanta, Atlanta, GA, USA

### Introduction

Ungulates are defined as animals with hooves. This simply implies that a portion of the terminal phalanx is encased in a sturdy hoof. Because many species of ungulates commonly live in open habitat types, they are often the most visible fauna on the landscape (Groves and Grubb 2011). As such, it may be surprising to some that there is a large gap in the research conducted on this fauna group, with generally little known about specific species (Groves and Grubb 2011), such as the elusive okapi.

Ungulates are found on every continent except Antarctica. They can be social or solitary, nomadic or territorial. While the Smithsonian Institution acknowledges 275 modern ungulates, Groves and Grubb (2011) recognizes 450 distinct ungulates through utilizing the Phylogenetic Species Concept as opposed to the more traditional Biological Species Concept. Even with the vast number of ungulate species, true ungulates are generally confined to two orders based on the number of toes they have: Artiodactyla (even-toed) and Perissodactyla (odd-toed).

Due to the diversity found among ungulates, this entry will focus on cognitive and behavioral traits of ungulates as a whole, occasionally referring to specific case studies and/or species.

### Evolution of Cognition

Cognition is defined as “the mental action or process of acquiring knowledge and understanding through thought, experience, and the senses” (Oxford Ungulate 2019). What led to the evolution of cognition in animals? It has been suggested that ecological problems, such as extractive foraging and memorizing resource location, as well as social demands such as group cohesivity and

reducing conflict, led to the necessity of cognitive evolution (Briefer et al. 2014). Advanced cognitive abilities enhance survival probability, leading to the success of a species. Interestingly, increase in brain size among carnivores and their prey species (particularly ungulates) seem to track each other closely, with ungulates leading in brain size (Dunbar and Shultz 2007). These findings demonstrate that brain size may be associated with other types of ecological flexibility.

Advanced cognition is often related to increased brain size. In ungulate species, the relationship between brain size and sociality is qualitative and not quantitative (Dunbar and Shultz 2007). Large relative brain size has been associated explicitly with pair-bonded monogamy. Ungulates which mate monogamously have been found to have substantially larger brains than polygamous ungulates (Dunbar and Shultz 2007) suggesting that sexual selection may be a more important factor driving brain evolution than sociality among ungulates (Dunbar and Shultz 2007).

Research on social learning and ecological selection pressures has mainly focused on the cognition of primates, birds, and carnivores (Shultz and Dunbar 2006). Social complexity, or lack thereof, in ungulates is currently under discussion. Shultz and Dunbar (2006) noticed a gap in the research and hypothesized that social and ecological factors could affect ungulate brain size. It was concluded that there was a positive relationship between brain size and sociality. Surprisingly, however, Shultz and Dunbar (2006) concluded that in their particular study that there was not a significant association between brain size and group size. This suggests that using group size to measure social complexity may not be the most relevant measure, although a relationship has been found previously between the two when measuring social complexity with a number of other taxa. In ungulates, who commonly have unstable grouping patterns, group size can be considered undefined. Estimating a characteristic group size may be more complex than counting individuals observed in a herd at a particular moment in time. Doing so may limit research findings on cognitive demands within ungulates. Shultz and Dunbar (2006) highlight that

“an unstable herd of several thousand antelope may not present the same cognitive demands as a smaller stable group, where individuals interact on a regular basis.”

In animals such as cetaceans and primates, scientists have discovered that their complex cognition and relatively large brains allow for social learning as opposed to learned behaviors driven by ecologically demanding environments (Marino et al. 2007; Reader 2003). Domestic goats, *Capra aegagrus hircus*, are a social species which show advanced cognitive abilities, such as colonizing new environments. Briefer et al. (2014) conducted a study on goats testing their social and physical cognition as well as long-term memory. Interestingly, the majority of goats were able to learn the task quickly, but did not learn more quickly after watching a different individual complete the task before trying it themselves. This indicates that the task was mastered through individual learning rather than social learning. The study suggests that relatively intelligent species, such as the goat, do not always exhibit a preference to learn socially. In contrast, learning might be more driven by the need to forage efficiently in ecologically demanding environments. Domestication has been shown to decrease brain size due to the relaxed selection pressures compared to the wild environment (Briefer et al. 2014). Perhaps a smaller brain size is still capable of complex social living and learning survival behaviors, without the necessity of social learning.

### **Social Structure: Gregarious and Solitary Ungulates**

Social structure varies greatly among ungulates. Blue duikers, *Philantomba monticola*, are monogamous, forming lifelong mating pairs, and are limited to specific home ranges. Red forest duikers, *Cephalophus natalensis*, are solitary with widely overlapping home ranges (Bowland and Perrin 2009).

Giraffes, *Giraffa camelopardalis*, live in social groups that individuals may enter and leave. There is no social segregation between sexes and age groups, and individuals tend to form weak

social bonds (Pendur et al. 2001). Associations are often dependent on sex and age, with young male giraffes interacting more frequently than other classes (Pendur et al. 2001).

Okapis, *Okapia johnstoni*, the closest living relative of the giraffe and known for their elusiveness, have quite the opposite social structure. Okapis are mostly solitary animals, most likely coming together only for mating. Males have been known to have home ranges overlapping with several females, which suggests polygamy within this species (Hart and Hart 1989). Spending most of their time in solitude is likely used as a predation defense (Hart and Hart 1989).

Sitatunga, *Tragelaphus spekii*, are commonly solitary; however, they have been documented in gregarious social structures when necessary for food consumption (Magliocca et al. 2002).

The above are just a few examples of the social structure variety witnessed in ungulates. Group living has advantages such as minimizing predation or allowing cooperation in locating food sources (Byrne and Bates 2007). However, it is a demanding evolutionary option. Group living has many disadvantages, such as resource competition. Competition for resources often results in group instability (Byrne and Bates 2007), which may be why giraffes form weak social bonds.

Evidence has shown that social living has been responsible for specialization in intelligence. As mentioned previously, ungulates show a pattern between the relationship of brain size and group size. Contradictory to what Shultz and Dunbar (2006) hypothesized, Byrne and Bates (2007) conclude that larger groups correlate to a larger brain size of the species, suggesting that social species have larger brains than solitary species (Pérez-Barbería and Gordon 2005). Brain tissue is metabolically expensive and so it is rational to assume that larger brained species must benefit highly from dealing with serious cognitive challenges (Byrne and Bates 2007), such as predator avoidance.

When a species is classified as solitary, some species change social systems depending on other, temporally changing, factors. Japanese serows, *Capricornis crispus*, are usually solitary but have been seen forming groups of two to four

individuals. These consisted of mostly mother-kid or male-female pairs with or without a kid. Although this species commonly defends its territories, several nonterritorial males have been observed. Japanese serows are considered monogamous, with a male's territory completely overlapping a female's territory. However, there have been exceptions of polygamous males, whose territory overlapped with two females' territory (Kishimoto and Kawamichi 1996).

### Physical and Social Environmental Impact

As prey species, ungulates are constantly having to modify their behavior and adapt to social and physical changes in their environment. Behaviors such as exerting energy to be vigilant towards predators in close proximity, changes in herd dynamics, and seasonal shifts in resource availability all require significant amounts of energy and adaptability. Reactive responses of any animal often pair down to flight or fight. Ungulates frequently partake in the flight behaviors to protect themselves against predators or startling changes in their environment. This response is an important aspect to maintaining or increasing individual fitness (Stankowich and Reimers 2015).

Physical and social environments often play a role in the flight response of individuals or groups of ungulates. Escape terrain proximity often influences the response of some ungulates (Takada et al. 2019). A Yellow-backed Duiker (*Cephalophus silvicultor*) would consider a densely vegetated forest to be escapable terrain, whereas a Siberian Ibex (*Capra sibirica*) would consider rocky areas such as inland cliffs and mountain peaks to be escape terrain if there was a predator or human disturbance in their midst (IUCN SSC Antelope Specialist Group 2016; Reading and Shank 2008). If either of these animals were at a distance from what the species would consider escape terrain, they would likely be more reactive to disturbances (Takada et al. 2019). For many ungulate species, like the Japanese serow (*Capricornis crispus*), the flight

response is consistently more apparent in relation to gender and if offspring are part of the herd (Stankowich 2008). However, when ungulates become isolated from predator populations, there is a reduction in predator vigilance (Blumstein 2006). This allows ungulates to alter their natural behavior patterns in a way that they can spend increased time choosing the most adequate mate, alter their herd sizes, become more resolute in maintaining territorial boundaries, and expand their foraging locations (Blumstein 2006). Berger (1991), Mysterud (2000), and Mooring et al. (2003) all came to a consensus that habitat use varies according to gender and that herds primarily consisting of females or females with offspring escape terrain more frequently than males do.

In a study on wild elk (*Cervus canadensis*) by Found and St. Clair (2017), it was discovered that there are different fitness benefits associated with strong and weak laterality. When the connection between the two hemispheres in the brain is weak (strong laterality), ungulates have quick responses to environmental stimuli, including humans (Found and St. Clair 2017). When the connection between the hemispheres is strong (weak laterality), it has been observed that those individuals have increased learning abilities and creativity (Found and St. Clair 2017). Similar to humans, ungulates demonstrate front-limb bias (left handedness vs right handedness) (Found and St. Clair 2017).

### Migratory Behaviors

Behavioral adaptability is one of the many pertinent skills that individual ungulates have in order to increase survival rates in changing environments. For ungulate species that live in more temperate environments, such as roe deer (*Capreolus capreolus*), their ecology illustrates that population density is determined by winter foraging conditions, while individual size and body condition are a result of summer foraging conditions (Klein 1965; Mysterud 2013). Ungulates that have a tropical home range, such as wildebeest (*Connochaetes taurinus*), may migrate due to seasonal changes in rainfall and plant nutrition or availability (Holdo et al. 2009).

Some ungulates such as elk (*Cervus canadensis*) are unhesitatingly able to habituate to environments with human disruption and have facultative migratory tendencies (Found and St. Clair 2017). Found and St. Clair (2017), concluded that elk that exhibited more laterality were more likely to migrate than those that expressed weaker laterality (Found and St. Clair 2017).

Ungulate migration can vary seasonally or by region due to annual environmental or anthropogenic changes. Whether foraging opportunities are intentionally distributed to ungulates or a byproduct of the increasing demand for crops, ungulate migration can change considerably (Jones et al. 2014).

### External Factors on Behavior

As behavioral research has advanced, it has become clear that there are numerous factors that can impact and alter behavioral patterns, from parasite relations to the effect of human-wildlife relationships. In a study conducted by Ezenwa and Snider (2016) on Grant's gazelles (*Nanger granti*), it was discovered that male Grant's gazelles transition between bachelorhood and territorial status several times throughout their adult lives. Territorial males have elevated parasite populations relative to individuals in a bachelor status (Ezenwa and Snider 2016). After experimentally reducing the parasite loads, it was found that males who were maintaining territories reaccumulated parasite burdens at faster rates than those who were not currently defending a territory (Ezenwa and Snider 2016). Because parasites utilize energy sources from their hosts, the adult males who had larger parasite counts had decreased frequencies of typical territorial and breeding behaviors (Ezenwa and Snider 2016). This resulted in the males with smaller parasite loads to be able to win territorial challenges, creating a cyclical rotation of dominant males, increasing genetic diversity within the population (Ezenwa and Snider 2016).

As human populations continue to expand into rural landscapes for recreation and livelihood, interactions between humans and wildlife are

becoming more abundant (Wittemyer et al. 2008; Yamashita et al. 2017). Accumulation of increased antipredator behaviors in ungulates that reside in close proximity to humans can cause detrimental effects to an individual's physiology and fitness (Cooke et al. 2014). Animals, particularly ungulates, tend to respond more forcibly when exposed to scenarios that they perceive as a more dangerous threat (Yamashita et al. 2017). The size of a group is inversely proportional to the amount of time that social ungulates spend being vigilant (Manor and Saltz 2003). Manor and Saltz (2003) studied the impact of human disturbance on vigilant behavior of a herd of mountain gazelle (*Gazela gazelle*). In findings, they stated that there was a negative relationship associated with the size of the herd and human disturbance (Manor and Saltz 2003). The gazelles that were in open areas with high levels of disturbance were in smaller herds than the gazelles that were in open areas with lower levels of disturbance (Manor and Saltz 2003). Population performance can be significantly altered by increased human disturbances due to the fact that changes in behavioral patterns can affect social structures of gregarious ungulates (Manor and Saltz 2003).

The flight behavior of guanacos (*Lama guanicoe*) and vicuñas (*Vicugna vicugna*) in relation to poaching was studied by Donadio and Buskirk (2006). These camelid groups were observed in two reserves where poaching was commonplace as well as a reserve where it was inconsequential (Donadio and Buskirk 2006). The camelids that habituated in the two reserves with more poaching reacted by fleeing 70% of the time they detected humans, whereas the groups of camelids that were observed in the park with less poaching only reacted 30% of the time when exposed to human presence (Donadio and Buskirk 2006). Likewise, elk (*Cervus canadensis*) who expressed less lateralization within their brain had stronger reactions to aggressive advances by humans; however, they were also the individuals that were able to more readily habituate to calm human presences (Found and St. Clair 2017). Behaviors that are dominant in lateralized individuals illustrate behavioral

resiliency, allowing those individuals to adapt more quickly to landscapes where humans are more common (Found and St. Clair 2017). Behavioral responses to human-wildlife conflicts may cause individuals to alter their selection process of habitats, resulting in the selection of poor habitats or the active avoidance of sufficient habitats (Battin 2004). Natural behaviors such as rearing young, resting, and grazing patterns can be significantly affected by negative perceptions of human exposure (Donadio and Buskirk 2006).

## Conclusion

As illustrated above, cognition and behavior are complex characteristics that are specific to each ungulate species. Social structures, brain size and laterality, environment, and external factors all have an important role in molding the unique mental constructs of ungulates. It is important to understand the delicate workings of and strong interplay between these characteristics when learning about and understanding the natural history of these animals in their vast variety.

## Unobservables

Jennifer Vonk

Department of Psychology, Oakland University,  
Rochester, MI, USA

## Synonyms

Imperceptibles

## Definition

Unobservables are hypothetical constructs, such as mental states, and physical forces including gravity and transfer of force. They are abstractions that do not take on physical form, so they cannot be perceived through any of the senses.

## Introduction

Unobservables are arguably the most abstract type of construct because they cannot be directly connected to physical features, although they can be correlated with observable events and objects. For example, gravity itself cannot be observed, but one can witness objects falling when released from support. One cannot directly see confidence, but it is manifested in postural cues and behaviors. Therefore, although unobservables are unavailable to the senses, they can be inferred and reasoned about. It is important to note that unobservables are undetected by senses other than the visual sense as well. That is, they cannot be heard, tasted, or felt any more than they can be seen. Unobservables are perhaps most interesting from the perspective of comparative psychologists in the sense that they can be inferred as causal forces giving rise to both physical and psychological events.

## Main Text

The Unobservability Hypothesis first formally posited by Vonk and Povinelli (2006) suggested that the capacity to reason about unobservables

may be one of the most significant cognitive capacities to distinguish human from nonhuman minds. Vonk and Povinelli presented substantial evidence that nonhumans represent various abstractions; for example, second-order relations, numerosities, and social relationships. Yet, even abstractions that can be directly tied to sensations, such as weight, appear challenging for other apes to reason about. An extensive series of studies with a group of chimpanzees suggested that apes do not view weight as a property of objects, but, rather, respond to the kinesthetic cues that objects of different weights produce during agent-object interactions (Povinelli 2012). Abstractions that represent hypotheticals, such as death, freedom, supernatural forces etc. might plausibly be expected to pose an even greater challenge because they are not reliably correlated with consistent observable features or sensations. Vonk and Povinelli questioned whether nonhumans could reason about physical forces such as gravity, and psychological attributes, such as thoughts, beliefs, and emotions. At the time of their hypothesis, the jury was out on whether even great apes could represent others' mental states (or their own), but the prevailing evidence suggested that they could not. In the past decade, researchers have become more amenable to the idea that other apes reason about at least some mental states in some contexts, but the ability is hardly as hegemonious as it is in humans.

## Mental States

When unobservables are consistently correlated with observable manifestations, such as the association between tears and crying vocalizations and sadness, it is difficult to tease apart the degree to which an organism has learned the outcomes associated with the observable features (in this case, tears and sounds of crying) or is drawing inferences based on the underlying and unobservable mental state (e.g., the emotion of sadness). Thus, the puzzle of whether nonhumans represent other minds, including thoughts, feelings, and beliefs, generally known as theory of mind (ToM), has captured the attention of psychologists for decades (Call and Tomasello 2008). Despite an

immense amount of energy and resources directed to this puzzle, researchers remain divided on the question of whether other animals reason about mental states. Mental states are just one class of unobservables and arguably, the most heavily researched. Perhaps the largest gains have also been made in this area. It appears that some species, predominantly other apes and members of the corvid family, have the capacity to correctly anticipate outcomes based on others' perspectives (Emery and Clayton 2001; Karg et al. 2015; Lurz et al. 2018), knowledge (Kaminski et al. 2008; Krupenye et al. 2016) and intentions (Buttelmann et al. 2017). However, even the most heralded studies, such as Krupenye et al.' (2016) observation that apes correctly anticipated a human agent searching where he thought an object would be, could be explained by the apes expecting the agent to search where he had last seen the object (or otherwise attended to it). Even when chimpanzees do appear to use their own experience to project internal states upon other agents, they do not appear to do so flexibly across contexts (Karg et al. 2015) the way that even human children do by the age of 5. These experience projection tasks hold the most promise for dissociating reasoning about unobservables from reasoning about observable correlates but have produced mixed evidence even in chimpanzees (Vonk and Povinelli 2011).

## Causal Reasoning

The larger question of whether animals reason about unobservables more broadly remains as elusive. As with mental states, causal forces typically manifest in observable events and behaviors such as object movements, and therefore, it can be equally difficult to determine whether an organism is reasoning about the manifestation or the underlying cause. Several clever paradigms have been designed in this area as well. For example, Blaisdell et al. (2006) examined whether rats were sensitive to whether an intervening action had occurred in associating cues with outcomes, thus exhibiting Bayesian causality. Even this careful design has been critiqued, however, by authors suggesting that response competition, i.e., lever

pressing, interfered with the rats' responses in this paradigm (e.g., Dwyer et al. 2009). As with the work on ToM, the high degree of association between unobservable causal forces and their outward manifestations challenges researchers' abilities to identify the mechanism underlying animal's decisions.

## Conclusion

Researchers will make little progress in determining whether other species reason about unobservables, and when this ability emerges in human ontogeny, until they disavow experimental paradigms that allow success by attending to observable correlates. Thus, the question remains central to comparative psychology as reasoning about unobservables could be the foundation for all of the distinguishing characteristics of humans, e.g., language, technology, teaching, culture, etc.

## Upsuck Hypothesis

Brittney Palode and Kristine O. Evans  
Department of Wildlife, Fisheries and  
Aquaculture, Mississippi State University,  
Mississippi State, MS, USA

## Synonyms

Insuck; Orgasm; Sexual climax; Sperm competition; Sperm retention

## Definition

The transfer of content, specifically semen, from the upper vagina to the cervix by way of rapid muscular movements in an orgasm.

## Introduction

Evidence for orgasm in nonhuman animals has been the subject of research for many years. Many studies have shown that mammals do indeed have orgasms, though the physical and psychological mechanisms are less well understood. Orgasms in males are necessary for the ejaculation of semen into the vagina or cervix of females. However, underlying causes of orgasm in females have long been a mystery. The upsuck hypothesis suggests that the contractions of the cervix during female orgasm may aid in the transport of semen to the ovary in many species. Although still controversial, evidence is compounding that supports upsuck as a potential causal mechanism behind female orgasm.

## Internal Female Reproductive Organs

Though their structure and function vary by species, in placental mammals, internal female reproductive organs typically consist of ovaries, fallopian tubes, uterus, cervix, and vagina. This is true of viviparous animals. The ovaries are the site of egg, or ovum, development. The fallopian tubes, also called the oviducts, transport the egg into the uterus. The uterus, often called the womb, houses and nourishes a fetus until birth. The cervix divides the vagina from the uterus. In many species the cervix stores sperm and acts as a filtration system. The vagina is responsible for accepting semen. Many invertebrate species, such as *Drosophila*, possess specialized organs called tubular seminal receptacles or spermathecae, which makes sperm storage possible. This storage gives the animal the option of delaying fertilization, which can be beneficial for the animal and its offspring's survival and fitness

when resources or conditions are inadequate (Amitin and Pitnick 2007). Spermathecae are rarely seen in mammals (Schnakenberg et al. 2012). However, many mammals (e.g., domestic dogs and many bat species) can store sperm with the help of the lining of the reproductive tract (Orr and Zuk 2014).

## What Happens During an Orgasm

According to Fox and Fox (1971), there are specific criteria for an orgasm. These criteria are changes in blood pressure, breathing pattern, and heart rate, changes in muscular tension, hormonal changes, and the emission of sound. Before an orgasm, the heart rate will begin to rise, genitals begin to swell with blood, and muscle tension begins to build up throughout the body. During an orgasm, the muscles in the vagina, uterus, and anus contract and then relax. The brain releases substantial amounts of chemicals, including the neurotransmitter dopamine and oxytocin.

Oxytocin has been found to correlate with the female orgasm in humans (Blaicher et al. 1999). Wildt et al. (1998) discovered that after the release of oxytocin, material was sucked up into the fallopian tube. It is thought that uterine peristalsis, or involuntary muscle contractions, may be mediated by oxytocin, leading to upsuck movements that facilitate sperm retention and transportation and may increase chance of successful fertilization (King et al. 2016).

## Upsuck Hypothesis in Action

The upsuck hypothesis was first proposed by Fox and Fox (1971) as “insuck.” Since then, the upsuck hypothesis has been studied in animals as well as humans. However, experiments to understand orgasm have existed for nearly a century. Evans (1933) performed one of the first experiments using dogs as subjects. After 25–50 s of ejaculation, semen was expelled into the vagina in regular spurts through a fistula. Evans found that, once the female dog reached orgasm, semen

was forced 20–25 cm. Krehbiel and Carstens (1939) performed a similar experiment with rabbits. They used substances such as methylene blue, janus green, and iodochlorol to inject into the vagina of the rabbits and showed rapid transfer from the vagina to the uterus.

Increases in sperm motility due to female orgasm drastically improve the time it takes spermatozoa to travel into the uterus. Using cows, VanDemark and Moeller (1951) found a decrease in time of spermatozoa travel from an hour and a half to two to three minutes following orgasm. Some scientists believe that sperm retention is also influenced by occurrence and timing of the female orgasm. Early work by Hartman and Ball (1930) showed that the transfer of semen or spermatozoa in rats required 30–60 s after ejaculation for successful transfer from the vagina to the uterus. After 2 min, spermatozoa were found in the fallopian tubes.

Studies have long been performed in humans to determine the importance of timing regarding sperm retention. Greater retention of sperm was found when the female experienced orgasm between 1 min prior and 45 min following male ejaculation. Low retention was present when the female climaxed more than 1 min prior to male ejaculation (Baker and Bellis 1993).

## Conclusion

Development, neuroendocrine drivers, and other causal mechanisms of upsuck in animals and humans are topics that remain in need of further study. The upsuck hypothesis may play an important role in maximizing fitness in many species. This hypothesis has also helped explain the role of female orgasms in the reproductive process.

## Introduction

Value transfer theory (VTT), originally advanced by von Fersen et al. (1991) to account for transitive inference performance in nonhuman animals, proposes that some of the positive or excitatory value of an S+ in a simultaneous discrimination transfers to the S− with which it appears. To illustrate, suppose that two stimuli, A and B, are presented simultaneously to an animal and that responses to A are always reinforced, whereas responses to B are always nonreinforced. A is an S+ and B is an S− (Fig. 1a). According to VTT, associative value accrues to the S+ directly through reinforcement, whereas the S− does not acquire value directly, because responses to it are never reinforced; yet, the S− does acquire value indirectly through its presentation with the S+. In

other words, some portion of the value of the S+ transfers to the S−.

Formally, the total associative value of any stimulus,  $i$ , participating in a simultaneous discrimination equals

$$V_i = R_i + \alpha \cdot V_{i+1}, 0 < \alpha < L \quad (1)$$

where  $R_i$  is the direct associative value conveyed by reinforcement to  $i$ ,  $V_{i+1}$  is the indirect value transferred to  $i$  from any S+ with which it is paired, and  $\alpha$  is a weighing factor that determines how much value is in fact transferred. The actual values of  $R_i$  and  $\alpha$  are to be determined empirically, but (a) the  $R_i$  values must be ordered according to the frequency or amount of reinforcement and (b)  $\alpha$  must lie between zero and an upper limit,  $L$ , ensuring that the associative value of a partially reinforced stimulus does not exceed that of a continuously reinforced. The attentive reader will notice that this is the equation of a line, with the total value of stimulus  $i$  increasing linearly with  $\alpha$ .

To illustrate, assume for simplicity that the direct value ( $R_i$ ) of a stimulus is either 2, 1, or 0, depending on whether the stimulus is always reinforced (S+), reinforced 50% of the time (S+/-), or never reinforced (S−), respectively. In the discrimination depicted in Fig. 1a (S+ vs. S−), the value of the S+ remains constant at 2, but the value of the S− approaches that of the S+ as  $\alpha$  increases. Logically, the value of the S− should remain below the value of the S+ and

**Value Transfer Theory, Fig. 1** Panel **a**: Schematic of a simultaneous discrimination. Two stimuli, A and B, are presented simultaneously. Choosing A is always reinforced (S+), whereas choosing B is never reinforced (S-). Panel **b**: Schematic of a task comprising two simultaneous discrimination. In one discrimination (A vs. B), choices of the correct option are always reinforced (S+), whereas in the other (C vs. D) choices of the correct option are reinforced only on half of the occasions (S+/-)

therefore  $L = 1$ , in this case (see Fig. 2, black vs. white circles). If the discrimination uses an S+/- instead of an S+ (i.e., S+/- vs. S-), then the value of the S+/- remains constant at 1 and the value of the S- approaches 1 as  $\alpha$  increases (see Fig. 2, black vs. white triangles).

**Value Transfer Theory, Fig. 2** Total associative value as a function of  $\alpha$  for an S+ and accompanying S- and for an S+/- and accompanying S-

### Evidence for VTT

Even though von Fersen et al. (1991) had no independent evidence for VTT when they initially proposed it, subsequent research has shown that it is a real phenomenon. Suppose that animals are trained concurrently on two simultaneous discriminations. One discrimination involves stimuli A and B with choices of A always reinforced and choices of B always nonreinforced, whereas the other discrimination involves stimuli C and D with choices of C reinforced half of the times and choices of D always nonreinforced (Fig. 1b). With these contingencies in place, A becomes an S+, C becomes an S+/-, and both B and D become S-. Using the same assumptions as before, the total associative values of A and C should equal 2 and 1, respectively, but in this case the associative values of the two S-, B and D, should differ. Because they are S- (i.e.,  $R_B = R_D = 0$ ) any associative value they may have must have been transferred from the positive stimulus with which they appear. Note, however, that B is presented with A, a stimulus with a total associative value of 2, whereas D is presented with C, a stimulus with a total value of 1. If  $\alpha$  remains constant across discriminations, then the value transferred to B should exceed the value transferred to D. In fact,

Fig. 2 illustrates this prediction. Comparing the white symbols, the figure shows that the value of an S− paired with an S+ (white circles) exceeds the value of an S− paired with an S+/- (white triangles), for all  $\alpha$ . Therefore, were we to assess preference between these two stimuli, we ought to find a strong preference for B. After training pigeons in this procedure (Fig. 1b), Zentall and Sherburne (1994) found a reliable preference for B over D, thus providing evidence for value transfer.

Subsequent research has shown that value transfer is not only reliable but also that its scope extends to multiple procedures and species. It has been shown that value transfers from the S+ to the S− when the frequency (e.g., Zentall and Sherburne 1994) and the magnitude of the reinforcer are manipulated (Siemann et al. 1996) and that it also operates when visual or odor stimuli are used (e.g., Kaiser and Means 2006; Zentall and Sherburne 1994). Importantly, even though most evidence comes from the discrete-trial simultaneous discrimination procedure, value also transfers in the free-operant version of this procedure, known as the concurrent-schedules procedure (Zentall et al. 1996b). Finally, value transfer has been found in at least three species: pigeons (e.g., Zentall and Sherburne 1994), rats (e.g., Kaiser and Means 2006), and humans (Lonon and Zentall 1999).

## Mechanisms of Value Transfer

The fact that two stimuli must be presented simultaneously for value to transfer suggests that the underpinning mechanisms are Pavlovian in nature. As animals learn to solve the discrimination, they typically observe the stimuli sequentially. Pigeons, for instance, tend to stand in front of one of the response keys prior to each trial. Consequently, on half of the trials, the S+ will be presented on that key and they will peck it. Yet, on the other half, the S− will appear on that same key and they will peck on the other key instead. Hence, on half of the trials, seeing the S− is followed, after a short delay, by the reinforcer (the time to move and peck the S+). This by itself can engender a Pavlovian relation between the S− and the reinforcer in two ways. One possibility is that the S− (the conditional stimulus, CS, in Pavlovian terminology) and the reinforcer (the unconditional stimulus, US) become directly associated through trace conditioning because the former is followed by the latter after a short delay. The other possibility is that the S+ mediates the association between the S− and the reinforcer; in other words, the mechanism involves second-order conditioning, for seeing the S− (CS<sub>2</sub>) is followed by seeing the S+ (CS<sub>1</sub>), which in turn signals the reinforcer (US). In either case, conditioned reinforcing properties (or value) should impart to the S−. Figure 3a illustrates these possibilities.

### Value Transfer Theory,

**Fig. 3** Panel a: Two possible mechanisms for value transfer. The dotted arrow represents direct conditioning between the S− (CS<sub>2</sub>) and the reinforcer (US). The dashed arrows represent second-order conditioning involving the S− (CS<sub>2</sub>), the S+ (CS<sub>1</sub>), and the reinforcer (US). Panel b: Devaluation test. By devaluing the mediator (the S+ or CS<sub>1</sub>), one can distinguish between the two purported mechanisms

One way to distinguish between the two hypotheses is to devalue the hypothesized intermediary in the second-order conditioning account. Suppose that the CS<sub>1</sub>-US association is extinguished via the repeated presentation of the S+ (CS<sub>1</sub>) with no ensuing reward. If the original training led to the direct association of the S− (CS<sub>2</sub>) with the reinforcer (US), then extinction of the CS<sub>1</sub>-US should not affect the conditioning value of the S− (CS<sub>2</sub>). If, on the other hand, the S− (CS<sub>2</sub>) becomes associated with the reinforcer (US) through its association with the S+ (CS<sub>1</sub>), then devaluing the latter should decrease the associative value of the former. Figure 3b illustrates these hypotheses.

Using the above-mentioned test, Zentall et al. (1996a) have shown that value transfer involves higher-order conditioning, not direct conditioning. The scenario is, however, more intricate because Zentall and colleagues also found that the association between the S− (CS<sub>2</sub>) and the S+ (CS<sub>1</sub>) is bidirectional. For instance, they observed that increasing the value of the S− (CS<sub>2</sub>) also enhances the value of the S+ (CS<sub>1</sub>), which suggests a form of within-event conditioning.

## Value Transfer and Contrast

von Fersen and colleagues (1991) proposed that positive value transfers from the S+ to the S− in simultaneous discriminations, but also admitted that negative value may transfer from the S− to the S+, leading to a decrease in the overall value of the S+. Subsequent research has shown that negative value does not transfer from the S− to the S+. Instead, if sufficient experience with the S− is allowed, the presence of the S− enhances the value of the S+ with which it is paired, a positive behavioral contrast effect.

Can we also find the opposite of positive value transfer from the S+ to the S−? The evidence suggests that value will transfer from the S+ to S− only when there is little experience

with the S− during training; if further experience with the S− is provided (e.g., via single-stimulus S− trials), negative contrast occurs. See Zentall and Clement (2001), for a review of value transfer and contrast effects in simultaneous discriminations.

In summary, in a simultaneous discrimination, positive value transfers from the S+ to the S−, but the S− seems to have little to no effect on the S+. Yet, if the consequences of responding to the S− are experienced repeatedly, each stimulus seems to counteract the value of the other. That is, positive and negative contrast occur.

## Conclusion

VTT was originally proposed to explain transitive inference in nonhuman animals. Even though it has since become apparent that transitive inference can arise in the absence of value transfer (for a review, see Vasconcelos 2008), value transfer has been found in a number of species and associated to a number of phenomena. These include, for example, the ambiguous-cue problem and other discrimination failures (e.g., Urcuioli 2006). Importantly, value transfer may also play a role in other apparently complex human phenomena such as the “basking in the reflected glory of others” or the “mere ownership effect.”

## Overview of the Nervous System

The nervous system is the system of the body involved in detecting changes (stimuli) in the internal and external environments, evaluating stimuli, and issuing an appropriate response (Saladin 2017). The nervous system is divided into two major subdivisions: central and peripheral (Fig. 1). The central and peripheral nervous systems do not work in isolation of each other. Rather, the central nervous system and peripheral nervous system are structurally and functionally continuous with each other. The **central nervous system (CNS)** is comprised of the brain and spinal cord, and it is comprised of predominantly of interneurons. The **peripheral nervous system (PNS)** is comprised of nerves (bundles of axons of neurons) and ganglia (group of neurosomas). The PNS has two subdivisions: motor (efferent) and sensory (afferent). The **sensory subdivision of the PNS** carries sensory information to the CNS by way of sensory neurons. Organizationally, the sensory subdivision is further subdivided according to where sensory information originates. The **somatic sensory division** sends sensory information from the skin and skeletal muscle to the CNS. The **visceral sensory division** sends sensory information from organs (smooth muscle) and glands of the body to the CNS. The **motor subdivision of the PNS** carries motor information to effectors by way of motor neurons. Organizationally, the motor subdivision is further subdivided according to the structure innervated. The **somatic motor division** regulates contraction of skeletal muscle. The **visceral motor division** (or **autonomic nervous system**) regulates contraction of smooth muscle and controls gland function. The autonomic nervous system also has a strong modulatory effect on cardiac muscle

**Vasal-Vagal Stimulation, Fig. 1** Organization of the nervous system. An overview of the subdivisions of the nervous system is shown in this figure

function, through it is not responsible for initiating cardiac muscle contraction (Boron and Boulpaep 2012).

### Autonomic Nervous System

The autonomic nervous system has two anatomically distinct subdivisions, the sympathetic and parasympathetic divisions, which innervate organs, blood vessels, and glands of the body. Both divisions of the autonomic nervous system originate in the CNS and utilize a two-neuron chain (preganglionic and postganglionic neurons) to reach effectors (Fig. 2). The sympathetic nervous system (SNS) originates in the lateral horn of gray matter in the thoracolumbar spinal cord. Walter Cannon, American physiologist and physician, discovered that the SNS is responsible for initiating the sympatho-adrenal stress response (“fight-or-flight”) when an animal is exposed to an acute stressor (Hall 2016). Cannon published his findings in the 1915 book *Bodily Changes in Pain, Hunger, Fear and Rage*. During the sympatho-adrenal stress response, sympathetic nervous system fires at a high rate. Through the effects of epinephrine and norepinephrine, the SNS increases heart rate, stroke volume, blood pressure, and ventilation;

triggers sweating; mobilizes glucose stores to raise blood glucose; decreases gastrointestinal motility; and triggers pupil dilation. These physiological responses to an acute stressor enhance an animal’s ability to fight or flee while facing a physical threat. A common misconception among students is that the SNS is only active during fight-or-flight. During rest, the SNS outflow is low, but basal sympathetic activity is critical for maintaining vascular tone (Saladin 2017). Sympathetic activity constricts arteries and raises vascular resistance. An increase in vascular resistance leads to increased arterial pressure. Thus, the sympathetic division has an important role in maintaining systemic blood pressure and adequate perfusion to organs, even during rest. The parasympathetic division originates in the brainstem and sacral spinal cord. It carries out “rest-and-digest” or “breed-and-feed” functions of the body. During rest-and-digest, the parasympathetic division utilizes acetylcholine to decrease heart rate, increase urine production, trigger pupillary constriction, and cause salivation in response to food stimuli. It has little impact on vasomotion of blood vessels with the exception of those supplying salivary and gastrointestinal glands and reproductive tissues. Much of the parasympathetic innervation of organs and blood vessels in the thoracic and abdominal cavities is

**Vasal-Vagal Stimulation, Fig. 2** Visceral motor innervation schematic. Both divisions of the autonomic nervous system innervate effectors by way of a two-neuron chain

provided by cranial nerve X, the vagus nerve (Boron and Boulpaep 2012).

## Central Control of Autonomic Function

Both divisions of the autonomic nervous system are regulated by structures of the CNS. The cerebral cortex is involved in higher brain functions and emotions. The cerebral cortex is known to have extensive neural connections with the hypothalamus' paraventricular nucleus (PVN). The paraventricular nucleus (PVN) of the hypothalamus exerts great influence over autonomic function; it contains a closed sensory-motor loop with both parasympathetic and sympathetic structures providing direct CNS influence over autonomic function. The PVN receives input from higher brain centers, such as the amygdala and hippocampus. The medial forebrain bundle (MFB) serves as the primary tract for information relay from limbic structures to the hypothalamus. The amygdala and hippocampus send inputs to the hypothalamus by way of the ventral

amygdalofugal pathway, fornix, and stria terminalis. The axons eventually join the MFB, supplying input to the PVN. Parvocellular neurons within the PVN also have axons that run to the dorsal motor nucleus of the vagus nerve, the rostral ventrolateral medulla, and intermediolateral column in the spinal cord. The axons of these neurons are part of the dorsal longitudinal fasciculus (DLF), a white fiber tract which begins in the paraventricular nucleus and terminates in autonomic control areas of the brainstem and spinal cord. The DLF also contains afferent neurons that allow for visceral afferent signals to be relayed to the hypothalamus (Llewellyn-Smith and Verberne 2011). A simplified schematic of central autonomic control is provided in (Fig. 3); the circuitry of central autonomic control is extensively covered in *Netter's Atlas of Neuroscience*.

## Vaso-Vagal Response

The vaso-vagal response (or reflex) is characterized by arterial vasodilation ("vaso") and hyper activity

**Vasal-Vagal Stimulation, Fig. 3** Major circuits of central autonomic networks. A simplified schematic of central autonomic networks is shown in this figure

of the vagus nerve leading to attenuation of cardiac activity (“vagal”). It is often accompanied by hypotension and bradycardia. In humans, the vaso-vagal reflex can cause a loss of consciousness due to decreased perfusion to the brain (van Lieshout et al. 1991). Loss of consciousness in such instances is referred to as vasovagal syncope (VVS). Vasovagal syncope can occur due to sudden blood loss, emotional stress, or painful stimuli. The precise mechanism of vasovagal syncope is not known. However, VVS is initiated when afferent pathways associated with the vagus nerve signal to higher CNS centers and autonomic nuclei in the brainstem to strongly stimulate the parasympathetic nervous system and eliminate sympathetic vascular tone (Boron and Boulpaep 2012) (Hall 2016). Little is known about the afferent pathway (the step from trigger to autonomic integration and central processing). However, the efferent pathways are well-established. During VVS, vagal outflow is increased, while sympathetic outflow is decreased. The decrease in basal sympathetic firing leads to passive vasodilation. As vagal firing increases, an abundance of acetylcholine is released onto the heart’s pacemaker (see “ECG/EKG” entry), decreasing heart rate (bradycardia). The decrease in heart rate reduces cardiac output (amount of blood pumped by heart in 1 min) and arterial

pressure. The drop in arterial pressure decreases perfusion of blood to the brain, causing a loss of consciousness or fainting (Fig. 4) (Boron and Boulpaep 2012). Fainting causes the body to assume a gravitationally neutral position, thereby offering a better chance of restoring brain perfusion (Blanc et al. 2015).

### Vaso-Vagal Reflex: A Survival Mechanism?

Vaso-vagal reflexes are often treated as pathological conditions. The pathophysiology has been studied, and therapies have been developed for treatment of VVS. Yet, the broader field of VVS research supports the idea that the vaso-vagal reflex is a biological phenomenon largely triggered (even in healthy individuals) by a specific set of circulatory conditions, such as excessive blood pooling and changes in body position. In specific instances, it may confer a survival advantage to a mammal. Several hypotheses have been developed to explain the evolution of vaso-vagal syncope in humans. One such hypothesis is particularly compelling: the clot production hypothesis. The clot production hypothesis states that the vaso-vagal reflex, by triggering bradycardia and lowering

**Vasal-Vagal Stimulation, Fig. 4** Vasovagal reflex. The information relay involved in a vaso-vagal reflex leading to syncope is shown in this figure

blood pressure, acts to limit blood loss during hemorrhage and is important in hemostasis (Diehl 2005; Levi 2005). There are several key pieces of evidence to support this hypothesis. Most instances of VVS occur in response to blood loss. Additionally, clotting factors von Willebrand factor and factor VIII are elevated following incidents of VVS that occurred during venipuncture (Casonato et al. 2003). In this context, VVS is likely acting as a protective mechanism to counteract hypovolemia during hemorrhage, thus improving odds of survival. Additionally, hemorrhagic shock animal models have been extensively utilized to elucidate the mechanism of vaso-vagal reflex (Schadt and Ludbrook 1991), as the vaso-vagal reflex can be reliably triggered in these animals. Emotion-induced vaso-vagal syncope is an interesting occurrence. Emotional disturbances originating in the cerebral cortex are relayed to the anterior hypothalamus (near hypothalamic autonomic control nuclei) and subsequently on to the medulla. Autonomic control centers in the medulla strongly activate the vagus nerve; the vagus nerve then evokes the cardioinhibitory effects discussed above. The signal also travels to sympathetic control centers and elicits sympathetic-mediated vasodilation by way of sympathetic nerves (Hall 2016). Further

studies are needed to completely elucidate the afferent pathways of emotion-induced syncope.

## Introduction

Vertebrates are a group of animals that appeared about 525 million years ago during the Cambrian period. Setting this group apart is an anatomical structure called the *vertebral column*, or *spine*. It is common to fish, amphibians, reptiles, birds, and mammals. Animals belonging to these groups are in the subphylum *Vertebrata* of phylum *Chordata*. Vertebrates have another unique anatomical structure called the *skull* or *cranium* toward the anterior end of the body that contains the animal brain. Hence, *Craniata* is another name for the *Vertebrata* subphylum. The structure of the skull can vary and, in early evolved vertebrates, such as lampreys and hagfish, does not include a jaw. The first jawed vertebrates emerged in the late Ordovician period but became common in the “Age of Fishes” (i.e., the Devonian period). Later vertebrate species were land animals (tetrapods). There are vertebrate species, like hagfish, which diverged early on during evolution, that retain only rudimentary vertebra instead of a continuous vertebral column.

The vertebral column is derived both embryonically and evolutionarily from a rod-like structure made up of cartilage-like material called *notochord* – a characteristic feature of all chordate animals at some point in their life span. The vertebral column supports and protects a hollow tube of nervous tissue called *spinal cord*.

## Fundamental Units of the Nervous System

The nervous system (NS) is an organized collection of two types of cells – *neurons* and *neuroglia* (or *glia*). Neurons are electrically excitable cells that can quickly transmit signals due to their three structurally unusual parts: *dendrite*, *cell body* (or *soma*), and *axon* (Fig. 1). Dendrites are fibrous projections from the cell body, which receive signals from other cells and transmit it toward the cell body, which processes the signal. The axon is a long fiber often branched at the distal end. The terminal end of each branch has a bulb-like structure called synaptic knob, which may contain synaptic vesicles filled with chemicals called

**Vertebrate Nervous System, Fig. 1** A schematic of neuron structure and signal transmission between neurons. Upper panel: Synaptic connection between two neurons. The presynaptic neuron is the one which releases neurotransmitters as a result of an action potential entering its axon terminal. The postsynaptic neuron builds up a new action potential in response to binding excitatory neurotransmitters. In the left lower part, the general structure of neuron is depicted. The dendrites receive internal or external signals and pass them to the cell body. The axon, a cylindrical process, transports signals from the cell body to the axon terminals and releases neurotransmitters into the

synaptic cleft to pass on to other cells. Each dendrite contains spines which increase the contact surface in order to form synaptic contacts. An axon can travel a few hundred micrometers or much further. For example, neurons in the spinal cord have very long axon projections, while they are very short in neurons that are part of local circuits in the brain. The branched end is broadened to form synaptic buttons or terminals. These participate in the communication either through electrical activity or through neurotransmitters. In the right lower part, an inhibitory synapse is exemplified

*neurotransmitters*. The axon facilitates antero-grade signal transmission from the cell body toward a site called the *synapse* or to a neuromuscular junction (Golgi 1906; Ramon and Cajal 1906). The synapse is the region formed between the membranes of a pre- and postsynaptic neuron, which may or may not be separated by a fluid-filled small space called the *synaptic cleft* (Fig. 1).

Neurons often communicate chemically through neurotransmitters by forming chemical synapses (Dale et al. 1936). Neurotransmitters

released by a presynaptic neuron diffuse through the synaptic cleft and bind to their specific receptors on the membrane of the postsynaptic neuron, thus passing on the signal (Fig. 1). Neurons may also communicate with each other directly through an electric synapse when they are too close to each other leaving no room for synaptic cleft formation. In this case, neurons electrically excite other cells by changes of their membrane potential elicited by the passage of ions and small molecules through the specialized proteins

linking their membranes at synapse (Hodgkin et al. 1952).

In contrast to neurons, glial cells are electrically unexcitable and are involved in nourishment, support, and maintenance of neurons. They form sheath-like processes of myelin around neurons to insulate signal transmission. Hence, they can modulate signal transmission executed by neurons. Glial cells also act as immune cells to protect neurons (Hickey and Kimura 1988).

## Anatomical Divisions of the Nervous System

The NS consists of two anatomical subdivisions: the central nervous system (CNS) and the peripheral nervous system (PNS) (Fig. 2). The CNS comprises the brain and the spinal cord, whereas the PNS is formed by ganglia and nerves. A cluster of neuronal cell bodies within the CNS is called a *nucleus*, while a cluster outside the

**Vertebrate Nervous System, Fig. 2** The organization of the nervous system and its parts in the human body. The central nervous system is composed of the brain and spinal cord (pink). The brain is anatomically organized into the

frontal, temporal, parietal, and occipital lobes. The peripheral nervous system (gray) is formed by spinal nerves that arise from the peripheral ganglia (cluster of neurons) for the innervation of different organs

CNS is called a *ganglion*. The nerve can be thought of as a collection of multiple fibers running through the animal body. Each fiber is a bundle of axons projecting from the cell bodies of neurons located in nuclei and ganglia that are located in the brain and spinal cord.

### Peripheral Nervous System

The PNS is organized as a set of ganglia and nerves and comprises any nervous tissue outside the CNS. Nerves form several branches that innervate every part of the body (Fig. 2). Nerves are classified as sensory, motor, or mixed nerves if they contain axons both from sensory and motor neurons or based on the signal transmission toward or away from the brain. The afferent nerves are projected from the sensory neurons (afferent), which receive input from sensory organs, such as the ears, eyes, nose, tongue, and skin, and pass the signal to the CNS, where it gets processed to elicit the appropriate sensation. The efferent nerves transmit signals from the CNS to motor neurons (efferent) for putting the organs and muscles into action such as contracting the skeletal muscles to execute voluntary movements of the arms (Sherrington 1906). The PNS is further subdivided into two parts: the somatic and the autonomic. The somatic NS consists of the nerves that branch out from the cell bodies of somatic sensory neurons located in the dorsal root ganglia of the spinal cord and innervate the skin, joints, and muscles. It regulates the movement of skeletal muscles. The autonomic NS contains nerves that innervate the internal organs, blood vessels, and glands. It controls involuntary actions such as heart rate, digestion, and perspiration.

### Central Nervous System

The CNS comprises the brain and spinal cord. In addition to the skull and the vertebral column, the CNS components are protected by a three-layered system of membranes called meninges. At tissue level, the CNS is divided into areas of gray and white matter. Gray matter contains a high proportion of neuronal cell bodies and their dendrites, glial cells, and capillaries. Gray matter is mainly clusters of neurons in the brain and spinal cord and in outer layers that line their surfaces. White

matter is mainly myelinated axons and appears white due to the myelin sheath.

The overall organization of the CNS is fairly similar among vertebrates. However, differences can be observed in some species for adaption to certain environmental settings. The spinal cord maintains its cylindrical shape in all vertebrates. The sensory information is received through the dorsal part of the spinal cord, while motor information leaves through the ventral part (Hawkins 1869). The number of nerves emerging from the spinal cord varies in different vertebrate species, from 31 pairs in humans to about 400 in snakes. Some animals have wide space between spinal segments, which correlates with an increased number of motor neurons (projecting from the space) that innervate the muscles of the limbs.

The brain controls all the processes carried out in the CNS and has three anatomical subdivisions: prosencephalon (forebrain), mesencephalon (midbrain), and rhombencephalon (hindbrain). The forebrain is a frontal part of the brain, which is covered with a large, wrinkly, outermost layer of the brain – the cerebral cortex (Fig. 3a). It consists of a left and right hemisphere, each of which is further divided into four major lobes: frontal, parietal, temporal, and occipital lobes (Fig. 2). There is another portion of the cerebral cortex folded deep within the fissure separating the temporal lobe from the parietal and frontal lobes. It is often included as a lobe called *insular* and, in humans, is believed to be involved in consciousness. These lobes together constitute the largest site of neural integration in the CNS and play key roles in memory, attention, perception, awareness, thought, and language.

The cerebral hemispheres have a great morphological diversity among different vertebrates. The cerebral cortex can be highly developed as seen in primates, or it can be underdeveloped as in lampreys, hedgehogs, or opossums. More developed cortices are folded in several places to increase the area of cortex that can fit inside the cranial cavity.

In spite of slight structural differences, the functions performed by cerebral cortex are fairly similar among vertebrates. For example, the hypothalamus is important for the physiological homeostasis in the body through the integration of

**Vertebrate Nervous System, Fig. 3** An overview of major anatomical structures of the nervous system. (a) In the brain, different anatomical structures exist with specific functions. One of these structures is the hypothalamus (b) which has ten major nuclei containing the cell bodies of the neurons of the hypothalamus. Their axons innervate the pituitary gland located below the hypothalamus, forming the hypothalamus-pituitary communication system. The

nuclei process information and axons communicate with the pituitary gland, which in response secretes specific hormones into the bloodstream where they travel to their site of action. The hypothalamic nuclei are labeled as follows: preoptic (pr), supraoptic (son), paraventricular (pvn), anterior (Ah), suprachiasmatic (sn), dorsomedial (dm), ventromedial (vm), arcuate (an), mammillary (mb), posterior (pn), hypothalamic nucleus

visceral (gut, glands, and inner organs) and somatic (the skin, joints, and muscles) information for the correct adjustment of the internal environment (Fig. 3b). The ventral thalamus establishes connections with the basal ganglia important for the motor behavior, and the dorsal thalamus is a relay site of different sensory pathways that connect with the cerebral cortex.

The midbrain is a vital connection point between the forebrain and the hindbrain. It is the topmost part of the brainstem, which connects the brain to the spinal cord. The upper portion of the midbrain has two principal pairs of nuclei called the superior and inferior colliculi. The superior nucleus processes visual signals before they are passed on to the occipital lobe. The inferior

nucleus processes auditory signals before they are passed through the thalamus to the main auditory processing center in the cortex.

The hindbrain is the lowest portion of the brain, containing the rest of the brainstem made up of the medulla oblongata, pons, and cerebellum. The medulla oblongata contains cardiorespiratory centers that can increase or decrease the cardiac and respiratory rates depending on the physiological needs. The pons is responsible for conducting signals from the brain down to the cerebellum and medulla and has tracts that carry the sensory signals up into the thalamus. The cerebellum is a small ball of dense brain tissue nestled right against the back of the brainstem. It is responsible for movement-related functions.

The anatomical disposition of the NS allows the dedication of different parts toward specialized functions. The terminals of axons projected from the cell bodies located in peripheral ganglia often innervate the body surface and visceral elements, where they form sensory receptors, which sense external stimuli. For example, touch sensations are processed by a type of mechanoreceptors called *Meissner's corpuscles* that are especially concentrated at the surface of sensitive areas such as fingers and lips. When fingers touch an object, these receptors sense the signal and send it to specialized centers in the brain, such as the hypothalamus, via the spinal cord. The spinal cord or the brain processes the signal and generates response such as the removal of fingers. The NS registers the responses against internal and external stimulus and improves them based on experiences.

### Anatomical Differences Between Vertebrate Species

The brain is further subdivided, anatomically and functionally, in slightly different ways among different vertebrate groups. The forebrain is well developed and subdivided in most tetrapods, but in many fish and some salamanders, the midbrain dominates. The embryonic vesicles that form the forebrain are usually paired and give rise to two hemispheres, like the cerebral hemispheres in mammals. The hindbrain is located anteriorly to the spinal cord and differs anatomically in various

vertebrate species. For example, the vagal lobe of the hindbrain is highly developed in fish and responsible for integrating the information from peripheral taste receptors located on the outer surface and the palate of the fish (Herrick 2005). However, mammalian counterpart is rather superficial compared to the highly developed lobe in fish. In mammals, the rostral portion of the solitary tract nucleus is homologous to the vagal lobe. Some vertebrates, such as the torpedo fish, have electric lobes in the hindbrain that innervate the electrical organ which produces an electric discharge to stun prey or for defense. The midbrain has well-developed optic lobe in birds, frogs, and other species that live in bright environments. Species that live in dark environments or have rudimentary eyes, such as lamprey, tend to have poorly developed optic lobes in their midbrains. In some vertebrates such as bats and whales, the inferior colliculus is enlarged for the highly efficient translation of sound waves. Olfactory bulbs in the forebrain are very well developed in vertebrates such as lampreys and rodents but only poorly in primates (Allison 1953).

### Embryonic Development of the Nervous System

The embryonic development of the NS is highly similar among vertebrates and proceeds through the neuralization and cephalization in three steps. First, the differentiation of the chordamesoderm (notochord) from the surrounding mesoderm begins, which provides signals for the patterning of an overlying neural tube. The notochord further provides a physical support to the developing vertebral column and NS. In the second step, the neural tube differentiates into an anterior and a posterior part. The anterior part develops into the three primary brain vesicles, forebrain, midbrain, and hindbrain, while the posterior part develops into the spinal cord. A set of specific signaling molecules and transcription factors called morphogens and neural determinants decides the regionalization and order in which parts of NS develop. In the third step, cephalization occurs when the neural epithelium gives rise to neural crest cells, and the ectoderm immediately adjacent

to the neural tube differentiates into localized regions of columnar epithelium cells called the epidermal placodes. The neural crest and placodes subsequently contribute to the vertebrate head development including the skull, connective tissue, cranial nerve, and sensory organs. The third step distinguishes vertebrates from all other animals. The resulting anatomy with a single hollow nerve cord topped by a series of cerebral vesicles is unique to vertebrates, while invertebrates have a ventral rather than dorsal system of ganglions.

## Closing Remarks

The NS is fairly similar in vertebrates with subtle differences in specialized structures and their functions. These specialized structures are present in animals that are adapted to specific environmental settings, which indicate that the ecological niche of animals has played a crucial role in shaping the evolution of nervous system. However, the basic cellular configuration is very similar in all these animals, as is the principle of neuronal communication through electric and chemical synapses.

## Introduction

With almost 70,000 recognized extant species, chordates form one of the most diverse of the classic animal phyla, behind only arthropods and mollusks. Vertebrates correspond to almost the entire diversity of Chordata, and are ecologically important mainly because of their large body sizes (although absolute numbers of biomass

belong to small-bodied animal groups), representing most of the top predators of food webs. Even though a collection and fossilization bias may be at play, favoring animals with hard tissues from aquatic environments, vertebrates also comprise a significant part of the fossil record.

Throughout their evolutionary history, vertebrates displayed a variety of locomotor modes and occupied a plethora of environments and ecological niches, including land, air, and secondary returns to aquatic environments. Feeding habits and mechanics, like herbivory (► [Herbivore](#)) and mastication, and reproductive and ontogenetic strategies, such as internal fertilization or larval development, are also extremely diverse and very important for their success.

Vertebrates are traditionally divided into five classes: fishes, amphibians, mammals, reptiles, and birds. This division reflects a pre-cladistic classification and two of them do not correspond to natural, or ► [monophyletic](#), groupings. What are usually referred to as “fishes” and “reptiles” represent paraphyletic groups under our current understanding of vertebrate evolution. However, since the use of such names is a paradigm that has yet to be overcome in the earlier stages of the educational system, this entry roughly uses the classic nomenclature, while presenting one more attempt in the process of overcoming the use of said names. Nevertheless, terms such as class and order were avoided, given they bear little to no phylogenetic significance.

Groups in these classical divisions display similarities that make them easy to distinguish from each other. This entry covers some key characteristic features, or synapomorphies, to identify these groups, but it should be kept in mind that they are mostly valid when considering extant groups only. Adding extinct lineages make these distinctions blurry because key features may either appear in different clades rather independently, or are complex characters that can be decomposed in simpler steps with their own tempo and mode – such as “flight.” Some characters may also refer to soft-tissue structures or ecological or physiological strategies that are difficult, if not impossible, to track in the fossil record, such as

mammary glands. This entry aims to provide an overview of when key features appeared or became established in different vertebrate groups, pointing to some evolutionary trends in these lineages.

## Vertebrate Relationship with Other Chordates

Despite Chordata not being the most diverse animal phylum, part of the interest in this group derives from the fact that humans belong to it. Extant chordates include, besides vertebrates, two other groups: Urochordata (tunicates) and Cephalochordata (lancelets). With advances in phylogenetic methods and new sources of data, like molecular and genomic, hypotheses of relationship between these three groups, as well as their relationship to other deuterostomes, were considerably debated in recent years. Despite this debate, the monophyly of extant chordates is corroborated by both molecular and morphological data. Morphological synapomorphies include the body stiffened by a notochord, a hollow dorsal nerve cord, a mucus-secreting gland named endostyle (considered homologous (► [Homology](#)) to the thyroid gland), a post-anal tail, and body musculature divided into chevron-shaped myomeres.

## What Makes a Vertebrate

The definition of Vertebrata is thoroughly discussed in the literature, and vertebrates are mainly recognized by the presence of a vertebral column and a specialized head. The vertebral column, which inspired the name of the group, is composed of several juxtaposed bony or cartilaginous skeletal blocks, the vertebrae. It covers or replaces the notochord, defines the major body axis, and participates in body support and movement.

The vertebrate head is recognized as a major evolutionary innovation, with several structures derived from neural crest cells and ectodermal placodes. The neural crest is derived from the embryonic ectoderm and participates in the

formation of the skull, gill arches, jaws (in jawed vertebrates), peripheral nervous system, among others. Ectodermal placodes are thickened regions in the body surface that, through interaction with the neural tube ectoderm, are involved in the formation of sensory organs, such as the olfactory, optic, and otic capsules and the lateral-line system. Although the neural crest and ectodermal placodes hardly fossilize, the presence of structures derived from these tissues in fossils help identify them as vertebrates.

Questions on how a megadiverse group such as vertebrates arose are quite frequent. One finding that brought important insights into this question regards gene duplication. Many vertebrate innovations are related to head structures: sensory and cranial ganglia, three paired special sense organs and their capsules, and gill arches. These are, in turn, associated to duplications in some regulatory genes (e.g., Homeobox genes ([► Homeobox Gene](#))) that probably occurred in the most recent common ancestor of all vertebrates. These regulatory genes control the segmentation and fundamental orientation of the body, and it is hypothesized that duplications of such genes, followed by divergence of one or both daughter genes, may underlie major evolutionary changes by allowing subsequent phenotypic change (Holland et al. 1994).

Therefore, significant genome changes affecting entire gene families, such as those observed in vertebrate genomes, correlate with significant changes in body organization. In this scenario, new genes are recruited for new roles after duplication (a process named exaptation), culminating in innovations in developmental trajectories (e.g., the involvement of neural crest and neural placodes in craniofacial morphogenesis, cephalization of the brain, and specialization of the segmented mesoderm), originating new structures that allowed rapid adaptive radiation (Holland et al. 1994). A second regulatory gene duplication probably occurred in the origin of gnathostomes (see below), in association with the appearance of several jaw-related structures, allowing another major adaptive radiation within vertebrates (Kuratani et al. 2016).

## The First Vertebrates and the Cyclostomes

Relationships among major vertebrates groups are shown in Fig. 1. Vertebrata is the group formed by the most recent common ancestor between lampreys and gnathostomes, and all its descendants. The group probably arose at the Cambrian (Fig. 1), and several related fossil taxa are of difficult placement in early vertebrate evolution. This may be due to the potential loss of apomorphic characters through fossil decay, resulting in a bias towards mistakenly placing fossils on the chordate stem. Among lineages with living representatives, the first one to diverge is the one that includes hagfishes and lampreys.

Hagfishes and lampreys are the only extant agnathans. The name “agnatha” refers to a paraphyletic assemblage of vertebrates including cyclostomes as well as several fossil lineages whose phylogenetic placement is controversial. “Agnatha” means “jawless,” and indeed these early vertebrates do not have jaws, a key morphological innovation that characterizes the clade that includes all the remaining vertebrates. Traditional morphological analyses and paleontological data usually recover a clade named **Craniata**, formed by hagfishes as the sister group of lampreys plus the remaining vertebrates, with the last two forming **Vertebrata**, while molecular analyses recover hagfishes and lampreys as sister groups instead, forming a clade termed Cyclostomi (Figs. 1 and 2), in which case Craniata and Vertebrata would be synonyms. This is still an ongoing debate, but the most recent inclusive analyses corroborates the cyclostome hypothesis.

**Myxinoidea** is formed by 82 extant species known as hagfishes. This clade originated in the Carboniferous and includes long-bodied, mud-burrowing scavengers, but also some filter-feeding and detritivore species. They use teeth-like keratinous structures to scrape flesh from their prey or to reel in worms that are filtered by the branchial basket. Their head region includes four pairs of tentacles surrounding the mouth and a single nasohypophyseal opening. The hagfish skeleton consists of the notochord and of cartilaginous structures forming an incomplete braincase,

**Vertebrates (Chordata), Fig. 1** Cladogram with the phylogenetic relationships of the major groups of Vertebrata, calibrated for geological periods. Groups with exclusively fossil representatives are shown in gray. Some clades are named at the nodes. Terminal names between quotation marks correspond to non-monophyletic groups,

which also are represented in phylogeny by doubled lines. Dashed lines correspond to period after group extinction. C: Cambrian; O: Ordovician; S: Silurian; D: Devonian; C: Carboniferous; P: Permian; T: Triassic; J: Jurassic; K: Cretaceous; Pg: Paleogene; N: Neogene; Q: Quaternary

elements supporting the branchial basket, and specialized mouth parts. Hagfishes also have prominent glands that produce a mucous secretion used for defense. Some hagfishes are sequential hermaphrodites, having male and female gonads, but only one of them is functional at a time.

**Petromyzontiformes** is formed by 47 extant species known as lampreys. The oldest records of the group date from the Devonian. Their body is

also elongated, but unlike hagfishes, at least half of the lamprey species are parasites, the blood of their hosts to which they adhere via their ovoid sucking mouth, which can also be used to hold onto rocks in a stream current. The mouth is supported by cartilage, and their cartilaginous skeleton includes a braincase, elements supporting the branchial basket, and rudimentary vertebrae. Marine lampreys are anadromous,

meaning that adults live in marine, salty or brackish waters, but return to freshwater to reproduce. The larvae, called ammocoetes, are suspension-feeders, but suffer metamorphosis and shift into parasitic adults. In some species, however, the adult is nonfeeding and dies soon after spawning.

Despite Myxinoidea and Petromyzontiformes being the only two jawless groups with extant representatives, several jawless vertebrates are known from fossils. **Euconodonts** is one of the most enigmatic of these groups, known for a long time only from their mouthparts. Pointed and comb-like phosphatic elements were found in Cambrian to Triassic rocks, but the organisms to which they belonged were unknown until the 1980s. New fossils including impressions of soft tissues allowed these elements to be identified as pharyngeal structures of long-bodied jawless vertebrates, the conodonts, which are probably closely related to cyclostomes.

**Anaspida** is another group of jawless vertebrates that is considered more closely related to cyclostomes than to jawed vertebrates. They vaguely resemble lampreys, having a single median nasohypophyseal opening, several gill pouches and a single anal fin. The phylogenetic placement of anaspids is unstable among different phylogenies due to some similarities with jawed vertebrates, such as the presence of a dermal skeleton and lateral fin folds, which might represent a starting point for the evolution of paired appendages. In fact, they were until recently placed closer to the jawed vertebrates, among several other fossil lineages usually referred collectively as “ostracoderms.”

## Ostracoderms and the Origin of Jawed Vertebrates

Several jawless vertebrate lineages commonly referred to as “ostracoderms” are now recognized as a polyphyletic grouping that includes lineages more closely related to Cyclostomi, successive sister-groups to gnathostomes, as well as some early gnathostomes. The term “ostracoderm” (meaning “shell-skinned”) refers to their extensive exoskeleton: an external armor of dermal

bones including large bony plates frequently fused at the anterior region forming a head shield, and smaller plates along the trunk.

Ostracoderms more closely related to gnathostomes (Fig. 2) exhibit a mineralized dermal skeleton formed by enamel, dentine, and bone. They arose around the Cambrian, and during their evolution, several characteristics shared with gnathostomes appeared, such as dermal odontodes with distinct root, crown and pulp-cavity in **Thelodonti**; cellular bone in **Galeaspida**; paired pectoral fins with associated musculature in **Osteostraci**. Therefore, several structures present in gnathostomes and responsible for their evolutionary success probably appeared in a stepwise manner during the diversification of these early vertebrates. A review on early vertebrate characteristics can be found in Donoghue and Keating (2014).

Jawed vertebrates form a monophyletic clade, **Gnathostomata**, characterized by a series of synapomorphies besides the jaws, and much of the insights regarding those synapomorphies came from developmental data (Kuratani et al. 2016). However, some of the major innovations in early vertebrate evolution are associated with the origin of the jaws. Gnathostome origin is also correlated to the duplication of regulatory genes. They have four Homeobox gene clusters, as opposed to two ancestrally in Vertebrata (Holland et al. 1994). The differential expression of regulatory genes at the anterior region of the head results in the differentiation between dorsal and ventral elements in the first visceral arches, enables the emergence of two distinct mandibular and hyoid arches, and leads to the enlargement of the forebrain and development of sensory systems.

Jawed vertebrates are also characterized by two paired appendages, the pectoral (anterior) and the pelvic (posterior), with associated girdles. In early gnathostomes, these appendages are present in the form of fins that, together with the dorsal and anal fins, have a great importance for maneuvering during swimming and are correlated to their success in habitat occupation. Later in the evolutionary history of tetrapod gnathostomes, these appendages are modified into limbs, and become very important for locomotion in the

**Vertebrates (Chordata), Fig. 2** Cladogram with the phylogenetic relationships of Vertebrata, focusing on groups traditionally referred to as “fishes”. Groups with exclusively fossil representatives are shown in gray. Some

clades are named at the nodes. Terminal names between quotation marks correspond to non-monophyletic groups, which also are represented in phylogeny by doubled, dashed lines

terrestrial environment. Theoretical works on the origin of the paired appendages concern the gill-arch theory, in which the appendages and girdles are considered modified gill arches, and the fin-fold theory, in which the appendages emerged from ventrolateral folds in the body wall. The latter hypothesis is supported by embryological studies on extant vertebrates, and is related to the differential expression of regulatory genes.

## Early Gnathostomes

Four major groups of gnathostomes are traditionally recognized, but their relationships, and even the monophyly of some of them, are still subject to dispute.

“**Placodermi**” is a group of Silurian to Devonian armored gnathostomes formerly considered part of ostracoderms (i.e., non-jawed vertebrates), but currently recovered as a paraphyletic grouping of basal gnathostomes (Fig. 2). Placoderms have a distinct cranial and thoracic armor forming a conspicuous, robust cephalothorax. They retain the plesiomorphic type of jaw suspension, the euautostylic suspension, with no participation of the hyomandibula. Placoderms were the first fishes to undergo a significant diversification event, with some of them reaching large sizes (like *Dunkleosteus*, with 25 m) and occupying apical ecological roles.

The “**Acanthodii**” have spines in all their fins, and spines developed from the fin-fold can also be present on their body wall between the ventral fins. This group is found from Silurian to Permian deposits (Fig. 1) and exhibits a mosaic of shark- and bony-fish-like features, which makes its placement problematic. Recent phylogenetic analyses place acanthodians as a paraphyletic group including some lineages more closely related to Chondrichthyes (Qiao et al. 2016) (Fig. 2), with whom they share the reduction of bony dermal plates and the presence of an intromittent reproductive organ, the clasper, which is a modified pelvic structure present in males. However, although typically associated to chondrichthyans, claspers are also found, besides acanthodians, in some placoderms.

Despite the confusion regarding the allocation of fossils at the base of Gnathostomata, most contemporary analyses agree in recognizing two monophyletic gnathostome groups with extant representatives: Chondrichthyes and Osteichthyes. They exhibit several noteworthy anatomical features, like a horizontal septum dividing dorsal and ventral blocks of body myomeres, elongation of the anterior (sphenoid) region of the head, oral teeth with pulp, dentin and enamel, and presence of a ventral cranial fissure. One important feature that arose at some point prior to the chondrichthyan and osteichthyan divide is the amphistylic suspension, in which there are two points of articulation between the jaws and the cranium: one through the upper jaw and another one through the hyomandibula.

## Chondrichthyes, the Cartilaginous Fishes

Chondrichthyans (► [Chondrichthyes Diet](#), ► [Chondrichthyes Navigation](#)) are fishes that completely lack dermal bones, being characterized by an endoskeleton formed by eventually calcified (but not ossified) cartilage, and are therefore known as cartilaginous fishes. Extant lineages include chimaeras, sharks, rays, and skates, with 1,282 species in 65 families of predominantly marine organisms (Fricke et al. 2020). The oldest records of the group date from the Early Silurian (Fig. 1), but fossil chondrichthyans, apart from isolated teeth and fin spines, are rare. As a consequence, the anatomy of early chondrichthyans is known only from a few fossil specimens, and the hypothesis of relationships between basal chondrichthyans have changed substantially in the last years (Qiao et al. 2016). Nevertheless, chondrichthyans probably arose earlier, in the Ordovician, and two major radiations can be identified: one in the Early Devonian and another one in the Jurassic.

Chondrichthyans are usually remembered as large pelagic predators, but representatives of the group occupy a broad spectrum of aquatic habitats, with diverse diet and anatomy (► [Chondrichthyes Morphology](#)). All

chondrichthyans perform internal fertilization, using the claspers as copulatory structures, and usually have a relatively small number of offspring. The noteworthy sensory system of chondrichthyans (► [Chondrichthyes Sensory Systems](#)) is probably one of the major reasons for the evolutionary success of the group. They have a very accurate olfactory system and the ability to sense weak electric fields through their ampullary electroreceptor organs.

Chondrichthyes are divided in two groups: Elasmobranchii and Euchondrocephalii (Fig. 2). **Elasmobranchii** can be diagnosed, among other characters, by a pectoral fin skeleton composed of three cartilaginous basals, numerous cartilaginous radials, and several keratinous ceratotrichia. Among elasmobranchs, **Xenacanthida** is a group of extinct large marine predators, found from the Carboniferous to the Triassic, with confluent anterior and posterior dorsal fins, and an anterior dorsal-fin spine. Members of **Ctenacanthidae** are found from Devonian to Triassic rocks and had separated anterior and posterior dorsal fins, both bearing spines with longitudinal ornamentation. Members of **Hybodontiformes** are found from Carboniferous to Cretaceous deposits, suffering a severe diversity decline at the end-Permian. They also have fin spines, besides hooked denticles on the surface of the head.

Considering elasmobranchs with extant representatives, the **Neoselachii** comprises the clear majority of living chondrichthyans. They have most of the classic chondrichthyan characteristics we commonly read in textbooks, including the synapomorphic hyostylic suspension, in which the palatoquadrate is supported by the hyoid arch, enabling great protrusion of the jaws. Neoselachians arose in the Triassic and have characteristic placoid scales. These scales have an anatomical structure like that of teeth, with pulp cavity, dentin, and three layers of enamel, and are therefore known as “dermal denticles.”

One of the main groups of elasmobranchs is **Galeomorpha**, a lineage with around 350 extant shark species that retain the plesiomorphic number of five gill-slits and the presence of an anal fin. Members of this group usually do not have a spiracle – a reduced, rounded opening, considered

the reminiscent of the primitive first gill slit. Some representatives of Galeomorpha are among the most famous “scary” sharks in popular culture, like the sand tiger shark (*Carcharias taurus*), tiger shark (*Galeocerdo cuvier*), white shark (*Carcharodon carcharias*), the hammerhead sharks (family Sphymidae), besides the large suspension-feeding whale sharks (family Rhinodontidae).

The other two elasmobranch clades form a monophyletic group diagnosed by the loss of the anal fin and the presence of an orbitostylic suspension, in which the palatoquadrate articulates to the neurocranium via the orbital process and the hyoid arch. **Squalomorpha** appeared in the Triassic and has around 160 extant species. Their representatives are usually unspecialized cold-water sharks, such as the dogfish sharks (family Squalidae). **Hypnosqualea** arose in the Jurassic. They are benthonic and have enlarged pectoral fins and spiracles. Their bodies, specialized for bottom-feeding, are flattened, with a ventrally positioned mouth, and mostly crushing teeth. With more than 600 species, the group includes the angel sharks, saw sharks, rays, and skates, being the most diverse among the extant chondrichthyan lineages.

The remaining chondrichthyans, **Euchondrocephalii**, include Chimaeriformes and several related fossil taxa. Extant representatives are usually very distinct anatomically, but many of the fossil taxa have an overall shark-like shape. Among fossil groups, the **Cladoselachidae** is one of the best known, with the genus *Cladoselache* represented by several well-preserved Devonian specimens. One interesting aspect of this group is that fossils with claspers have not been found to date.

**Holocephali** is a chimaeriform group composed of 56 living species of chimaeras and closely related fossils. The oldest holocephalan is known from the Devonian, and they can be recognized by the synapomorphic presence of a unique holostylic suspension, in which the palatoquadrate fuses to the neurocranium, and the suspension has no participation of the hyoid arch. Living holocephalans bear a spine in the first dorsal fin and their branchial arches are covered by a single gill opening. Chimaeras are mostly

deep-water organisms, and because of that are much less studied than elasmobranchs.

## Osteichthyes: Origin and Fossil Groups

Bony fishes were given this name to contrast with other groups that have a cartilaginous internal skeleton (i.e., cyclostomes and chondrichthyans). However, mineralized tissues are far more complex than this simple dichotomy and, to some extent, this name also implies in a traditional view on vertebrate evolution, in which an ancestrally cartilaginous endoskeleton became more robust as it became ossified. Although some bony tissues do have cartilaginous precursors, some others do not (dermal or intramembranous ossifications). Furthermore, while a cartilaginous skeleton may indeed be plesiomorphic for vertebrates, both the paleontological record and recent molecular studies seem to indicate that the absence of bone in chondrichthyans is actually secondary.

The first records of osteichthyans date from the Late Silurian (Fig. 1), but some fossil forms are of disputed placement. Several characteristics present in osteichthyans actually appeared before the origin of the group, and are seen in placoderm lineages. In early bony fishes we find an ossified internal skeleton, but also a superficial skeleton formed by dermal bones and scales, and there may even be interactions (for example, fusions) between endochondral and dermal bony elements. In later osteichthyans we see a trend towards reduced ossification of both scales and dermal bones, while a more complete ossification of the internal skeleton takes place. Osteichthyans can also be identified by having dermal fin rays (lepidotrichia) supporting their fins, the presence of a gas bladder that originates either the swim bladder or the lungs, and assimilation of elements of the lateral line canals into the skull. Osteichthyes are divided in two groups: Actinopterygii and Sarcopterygii.

Actinopterygii is usually defined by a combination of plesiomorphic features that are found more generally in osteichthyans, and apomorphic traits found in more derived groups, meaning that

not all actinopterygians will show them. Early actinopterygians inherited as plesiomorphies, for example, several radial elements articulating between the pectoral fins and girdle, an endocranium ossified as a single structure, and scales covered by a ganoine layer. However, they also exhibited some novelties, like a modified heterocercal caudal fin that is transformed into a homocercal fin in more derived actinopterygians, a single dorsal fin that is also further modified into two dorsal fins or more in derived groups, and modifications of facial muscles associated with jaw suspension and movement (Datovo and Rizzato 2018).

**Sarcopterygii** also retains some osteichthyan plesiomorphies, like the presence of two dorsal fins and a heterocercal caudal fin that becomes modified into diphyccercal caudal fin in some groups. Sarcopterygian novelties include a single element articulating the fins and girdle (humerus and femur), an endocranial articulation between the etmosphenoid and otoccipital regions, that is secondarily lost in tetrapods, and scales covered by a cosmine layer.

## Actinopterygian Diversification

Actinopterygians are called “ray-finned fishes” because their fins are supported by lepidotrichia, whose controlling muscles are located within the body wall. However, lepidotrichia are also present in sarcopterygians. Actinopterygians currently comprise more than 34,000 species (Fricke et al. 2020), of which about 44% are known exclusively or predominantly in fresh waters.

Three major evolutionary trends can be described as driving actinopterygian evolution: increase in endoskeletal ossification and reduction of scales and of cranial dermal bones; a transition from biting to sucking mouths; and the development of more symmetrical caudal fins. These derived features are found in teleosts and are believed to account in great part for their evolutionary success.

Actinopterygians went through two major evolutionary radiations: the first between the Devonian and Carboniferous, and the second

starting in the Mesozoic and lasting into the Cenozoic (Fig. 1). Despite the first actinopterygians being broadly similar in shape, they were relatively diverse by the end of the Devonian, and were not greatly affected by the Late Devonian mass extinction. Novel cranial morphologies appeared in Early Carboniferous forms, so much so that actinopterygians were the dominant fish group by the end of the Permian (Friedman 2015). In the Early Triassic, actinopterygians went through an adaptive radiation, increasing their taxonomic dominance, especially in marine environments. At this point, the first neopterygians arose (Fig. 2), already showing a major trophic divergence among taxa.

Non-teleost lineages, such as **Cladistia**, **Acipenseriformes**, and **Holostei** (Fig. 2), used to be viewed as ecologically restricted groups, but while this may be partially true today, extant non-teleosts are poor representatives of their former biodiversity (Friedman 2015). For instance, “**Palaeonisciformes**,” a paraphyletic grouping of early actinopterygians, were globally distributed, occupying a wide range of ecological niches, and represent most of Paleozoic and Early Mesozoic actinopterygian diversity. Living cladistians, acipenseriforms, and holosteans show striking anatomical specializations when compared with fossil taxa.

## Teleostei

The most speciose actinopterygian lineage is **Teleostei**, which includes approximately half of all extant vertebrate species. Teleosteans originated in the Triassic and exhibit the most derived conditions in neopterygian evolutionary trends. Maxillary specializations arose several times in the group. Several fin specializations are observed, especially in the caudal-fin skeleton, creating a symmetrical homocercal tail. A whole-genome duplication event occurred in the ancestor of crown-group teleosteans, which might be associated with the great radiation event that occurred in this group.

The phylogenetic relationships of the major teleostean clades are not fully resolved, but some large

groups are recurrently retrieved as monophyletic, including **Elopomorpha**, **Osteoglossomorpha**, **Otocephala**, and **Euteleostei** (Fig. 2). Among these, the Otocephala are especially interesting because they possess a connection between the swim bladder and the inner ear, which is used to improve hearing. The major group of otocephalans is Ostariophysi, for which the otophysic connection is formed by the Weberian apparatus, a highly specialized structure composed of modified vertebral elements. This group includes cyprinids, loaches, characids, tetras, catfishes, and knifefishes, comprising more than 10,000 species and about 68% of all freshwater fish diversity (Nelson et al. 2016).

Finally, Euteleostei encompasses almost two thirds of actinopterygian diversity, with around 20,000 species distributed in 50 orders, and occupying the most diverse environments, including pelagic habitats (Nelson et al. 2016). This group originated in the Cretaceous, and is the major component of the second great actinopterygian radiation that started in the Cenozoic. The most species-rich lineage is **Acanthomorpha**, whose representatives typically have the anterior fin rays of both dorsal and anal fins forming spines. The relationships within Euteleostei, and especially within Acanthomorpha, are somewhat unstable, since morphological and molecular phylogenetic hypotheses usually strongly disagree.

## The Other Branch of the Osteichthyan Phylogeny: Sarcopterygii

Sarcopterygians are called “lobe-finned fishes” because their appendages are supported by well-developed endoskeletal elements whose controlling muscles project extensively onto them, in contrast with actinopterygians. They also have an intracranial articulation that may have served at first for feeding, allowing them to secure prey more firmly, but later aided in buccal pumping and breathing. Sarcopterygii includes Tetrapoda, which comprise roughly half of the extant vertebrate diversity and is found predominantly on land. The commonly used term “sarcopterygian

fishes” refers to a paraphyletic assemblage of several fossil lineages and a few extant species, excluding the tetrapods.

The earliest sarcopterygians date from the Silurian (Fig. 1). Apart from stem-sarcopterygians such as *Guiyu* and *Psarolepis*, whose placement has been disputed, the earliest sarcopterygian lineages to diverge were **Onychodontiformes** and **Actinistia** (Fig. 2). The latter includes coelacanths, comprised of many fossils and only two (maybe three) living species in the genus *Latimeria*. Coelacanths are found in Devonian deposits and were thought to have been extinct in the Cretaceous until 1938, when a living specimen was found off the South African coast by Marjorie Courtenay Latimer. Still not much is known about coelacanth biology, but they apparently have a modified lung which is calcified in fossil species, but filled with fatty tissue in extant ones. Meanwhile extant coelacanth species are found in deep seas and are very alike, fossil taxa had a great body size diversity and were also found in shallow, fresh waters. Coelacanths can be further diagnosed by their diphycercal caudal fin, a trait found more broadly among early sarcopterygians.

Another sarcopterygian lineage with living representatives is **Dipnomorpha** (Fig. 2), the lungfishes, with several fossil taxa and three extant genera: *Neoceratodus*, *Protopterus* and *Lepidosiren*. Although fossils are known from all continents, living lungfishes are restricted to Australia, Africa, and South America respectively, and are famous for breathing air through alveolar lungs. While fossils are also found in marine environments, living species are restricted to freshwater habitats. Modern lungfishes lack a cosmine layer in their scales and have the skeleton composed mostly of cartilage. They have dentigerous plates which are used in a durophagous diet for crushing shelled invertebrates. *Protopterus* and *Lepidosiren* have reduced, slender fins, and are known for forming burrows in which they survive dry periods (aestivation). This is a conserved behavioral and physiological trait, and many fossils are found in fossilized burrows. Their head skeleton is much modified and specialized for making the burrows.

## The Invasion of Land

**Tetrapodomorpha** includes fossil groups more closely related to tetrapods than to dipnomorphs, and the tetrapods themselves (Fig. 2). As a trend, tetrapodomorphs show progressive development of the zygapophyses, vertebral processes that couple with adjacent vertebra and increase stiffness of the vertebral column and its ability to resist torsions and flexions, thus providing better support for the body on land. The ribs extend in length and become an important attachment site for the coastal musculature that supports the body. The appendicular system becomes increasingly more integrated with the axial system, and the pectoral girdle eventually loses connection with the skull. The differential development of postaxial and preaxial digit-like elements in the appendages increases their participation in locomotion, while also reducing the role of the tail. Several works point out that this differential development is due to the alteration in the expression of regulatory genes (e.g., Tanaka 2016).

Breathing on land is more challenging than breathing in water, even though the air has a higher oxygen content, because respiratory surfaces suffer with desiccation. The excurrent, posterior naris, which appeared in the origin of gnathostomes and participated only in olfactory chemoreception, gains a connection with the oral chamber, forming a choana (probably in the ancestral of tetrapodomorphs and lungfishes). With the choana, dissection is reduced. The excurrent naris appeared in the origin of gnathostomes, and participated only in olfactory chemoreception. Finally, in the terrestrial environment, electroreception and mechanoreception via the lateral-line system lose prominence, whereas photoreception and oral and olfactory chemoreception become more important for perceiving the environment.

Stem-tetrapods include **Rhizodontiformes**, **“Osteolepiformes,”** and **Elpistostegalia** (Fig. 3). These groups comprise several fossils of great importance for understanding the transition to land, even though recent advancements in the functional morphology of tetrapodomorphs indicate that its representatives, once seen as more salamander-like, are now believed

**Vertebrates (Chordata), Fig. 3** Cladogram with the phylogenetic relationships of Tetrapodomorpha. Groups with exclusively fossil representatives are shown in gray. Some clades are named at the nodes. Terminal names

between quotation marks correspond to non-monophyletic groups, which also are represented in phylogeny by doubled, dashed lines

to have been much more aquatic. Some famous extinct tetrapodomorphs are *Eusthenopteron*, *Panderichthys*, and *Tiktaalik*. While

*Eusthenopteron* retains a “fish-like body, well adapted for pursuit within the water column” *Panderichthys* and *Tiktaalik* provide a glimpse in

the appearance of limbs. *Panderichthys* and *Tiktaalik* are Devonian taxa believed to be largely aquatic, but making extensive use of the substrate for locomotion. They likely inhabited waters shallow enough to require body weight support, such as the lower reaches of tropical river systems, their deltas or estuaries (Ahlberg 2018). Several of their anatomical features were probably advantageous for breathing air in these shallow waters with low oxygen content.

## The First Tetrapods

Of the five groups into which vertebrates were traditionally subdivided, amphibians, reptiles (including birds), and mammals comprise Tetrapoda. This clade includes, therefore, all terrestrial vertebrates, which represent roughly half the extant vertebrate diversity, with about 35,000 extant species. The first tetrapods show a mosaic of features, some connecting them to aquatic environments, like internal gills, fins, and extensive lateral line canals, and some to land, like the anatomy of their limbs and vertebral column. Hypotheses on the phylogenetic relationships of the first tetrapods has changed in recent years, but the group can be characterized by the presence of a specialized atlas and axis complex, a structure formed by the first two cervical vertebrae that articulates the head with the remainder of the vertebral column and facilitates head movement out of water. Tetrapods are also characterized by the presence of two pairs of limbs formed by three segments, namely, stylopodium (proximal), zeugapodium (middle), and autopodium (distal), the latter formed by skeletal articulating elements (carpals and tarsals) and digits. Furthermore, the stylopodium is formed by the humerus in the fore- and the femur in the hind limb; and the zeugapodium is formed by the radius and ulna, and tibia and fibula, respectively. Finally, the autopodium is represented by the manus and pes, and is formed by skeletal articulation elements (carpals and tarsals), in addition to the digits.

A characteristic typically associated with tetrapods is the presence of five digits, a condition named pentadactyly. Basal tetrapods, however,

commonly exhibit more than five digits (e.g., *Tulerpeton*, *Ichthyostega*, *Acanthostega*). Digits first appeared in forms that were still aquatic, suggesting they may have originated as an adaptation to shallow aquatic environments. The pentadactyl condition, on the other hand, is consistently found among more terrestrial forms, and it was established early in the evolution of tetrapods (Ledbetter and Bonnet 2019). Among tetrapods, several independent instances of reduction in the number of digits, or of limbs, occur. Instances of polydactyly (i.e., more than five digits) also occur, especially among secondarily aquatic forms such as cetaceans and ichthyosaurs, but these are rare, probably due to developmental constraints associated with the establishment of pentadactyly (Shubin et al. 1997).

The basalmost representatives of **Tetrapoda** are *Acanthostega* and *Ichthyostega* (but see Ahlberg 2018 for alternatives), both possessing fingers and toes, in addition to an enlarged pelvis and a flexed elbow. Despite them being from the latest Devonian (Fig. 1), fossil footprints (Stössel et al. 2016) suggest the first tetrapods date from at least the Middle Devonian, indicating a gap in the fossil record. Morphofunctional data suggest *Acanthostega* might have been a fully aquatic animal (Ahlberg 2018), while *Ichthyostega* have unambiguous adaptations for terrestrial life, such as a strengthened vertebral column and a reduced operculum – despite probably still having limited locomotion abilities on land.

Other fossil groups of early tetrapods include forms other than the usual “fishapods”, such as **Whatcheeridae**, **Colosteidae**, and **Adelospondyli** (Fig. 3). The latter two are elongated animals with limbs reduced or absent. Recently, this diversity increased with the addition of some **Aistopoda**, a clade of similar animals classically assigned to the amniote stem (Pardo et al. 2017b), suggesting high locomotory and functional diversity in these transitional forms.

## The Tetrapod Divise

Tetrapoda is a crown-group divided into two lineages: **Temnospondyli**, which includes living

amphibians, and **Reptilomorpha**, containing amniotes and all fossil groups more closely related to them than to temnospondyls (Fig. 3). The split between these two groups occurred in the Middle Devonian. Fossil temnospondyls were largely restricted to semiaquatic environments, but rather diverse in form. Most were superficially salamander-like, but there were also crocodile-like groups such as **Trematosauridae** (Fig. 3) and some sail-backed species. Although living amphibians are characterized by a smooth skin, the body of fossil temnospondyls was extensively covered with osteoderms. Stem reptiliomorphs include “**Lepospondyli**”, a group of fossil amphibians with some limbless, elongate forms regarded as more closely related to amniotes than to temnospondyls and whose monophyly is disputed, and two groups of large-bodied reptile-like species, **Seymouriamorpha** and **Diadectomorpha** (Fig. 3). Potential larval stages are known for seymouriamorphs but not for diadectomorphs, making them ideal models of progressively more terrestrial groups. Recent phylogenetic analyses, however, have recovered Diadectomorpha among synapsids (Klembara et al. 2020).

### Living Amphibians and Their Relationship with Fossils

Living amphibians comprise more than 8,200 species divided in the orders Anura, Gymnophiona, and Caudata. They are commonly known for having a two-part life cycle that usually includes an aquatic larva and a terrestrial adult, these stages being separated by a process of metamorphosis (although some species exhibit direct development and do not metamorphose). The most conspicuous changes during metamorphosis are the loss of the gills and the appearance of limbs, when present. The caudal fin of the larva also is resorbed during metamorphosis, being replaced by the tail in salamanders or reabsorbed in frogs.

Caecilians are fossorial snake-like animals included in the group **Gymnophiona** (Fig. 3), meaning “naked snake” in reference to the smooth, humid aspect of their skin. Although fossil forms bear rudimentary limbs, all living

caecilians are limbless, and some forms retain ossified scales, even though most species lack them. With only about 214 species, and due in part to their secretive life habits, caecilians are considered one of the least known vertebrate groups. Some species have glands on their skin that secrete toxins, and venom dental glands were recently identified (Mailho-Fontana et al. 2020). A conspicuous characteristic of the group is the very compact, robust skull that they use for burrowing in the substrate. Their eyes are reduced, and they bear a unique mechanosensory organ on the head named tentacle. Unlike salamanders and frogs, caecilians have an intromittent organ called phallodeum, used for internal fertilization. Some caecilians are viviparous, lacking a larval stage, and in some species, the newborn use specialized teeth to feed on the lipid-rich skin of their mother (Wilkinson et al. 2013).

Salamanders, newts, and tritons are included in **Caudata** (► [Caudata Cognition](#), ► [Caudata Locomotion](#), ► [Caudata Sensory Systems](#)), while frogs and toads are included in **Anura** (Fig. 3). Despite the indirect development being widespread in both groups, some salamanders never metamorphose, remaining in the aquatic environment and retaining their gills and caudal fin. One example is the famous Axolotl, *Ambystoma mexicanum*, an important model organism for studies on development, evolution, and regeneration. Some anurans, on the other hand, have direct development, with the absence of a larval stage.

Anurans display a diverse array of reproduction strategies that include the use of elaborate calls for territory defense and for attracting partners. Males of some species oftentimes engage in violent combats. Anuran eggs can be laid in water bodies, leaves, or even in completely terrestrial environments. In these cases, the parents may produce a foam nest that protects the cluster against dehydration. Many species also display several forms of parental care, including species that carry their eggs and larvae in their bodies (in skin pockets, dorsal pouches, vocal sacs, or the stomach, for example) until they metamorphose into froglets.

While salamanders have a long body and tail and relatively short legs, frogs and toads have

short bodies with well-developed hindlimbs, features commonly associated with their jumping locomotion. In the anuran pelvis, the ilium is extremely long and the caudal vertebrae are fused into the urostyle, a rod-like structure that acts as a propulsion mechanism. Given their highly vocal behavior, hearing is very important for anurans. All living amphibians possess a special hearing organ named papilla amphibiorum for detection of low frequency sounds, but some anurans also have a differentiated sound detecting mechanism through the operculum, a cartilaginous flap in the otic capsule, for very high frequency sounds. Anura includes the Clawed Frog, *Xenopus laevis*, an important model organism for developmental biology, cell biology, and neuroscience.

The clade containing the three mentioned groups of living amphibians is called **Lissamphibia** (Fig. 1), but the composition and placement of Lissamphibia has been subject of heated debate. Phylogenies generally agree that salamanders and anurans are more closely related to each other, united in a clade named **Batrachia**. In contrast, the relationship between batrachians and caecilians is more controversial, especially when considering fossils. There are three main phylogenetic hypotheses for living and fossil amphibians. The temnospondyl hypothesis places lissamphibians within the aforementioned Temnospondyli (Fig. 3), the lepospondyl hypothesis places them within Lepospondyli, and the polyphyletic hypothesis separates caecilians and batrachians, considering caecilians belonging to Lepospondyli and batrachians to Temnospondyli. While the temnospondyl hypothesis is favored over the other two, the monophyly of Lissamphibia within temnospondyls has been recently challenged (Pardo et al. 2017a). This controversy illustrates how much of our understanding of the relationships between living groups depends on the knowledge of the relationships between fossil forms. Surely, the discovery of new fossil amphibians as well as new studies of living and extinct forms will provide a better understanding of the relationships between living and fossil amphibians.

## Amniotes

**Amniota** comprise reptiles (including birds, see below) and mammals, with about 27,000 living species and many fossil lineages (Fig. 3). The group originated in the Late Carboniferous (Fig. 1). The main feature of amniotes is the cleidoic or amniotic egg, which has three embryonic membranes in addition to the yolk sac, namely, the allantois, amnion, and chorion. The chorion is involved with gas exchange, while the allantois stores wastes from the embryo (Kardong 2012). The amnion forms the amniotic sac containing the amniotic fluid, which prevents dehydration of the embryo in addition to offering mechanical protection. Amniotic eggs also have a protective shell that is either calcified or leathery, but permeable to gas exchange. The shell is lost in viviparous mammals, but is retained in the oviparous monotremes. Inside the egg, the amniote embryo develops without a larval stage or metamorphosis. These features render the amniotic egg as more suitable for terrestrial environments.

The presence of an outer layer of skin composed by keratinized cells, which helps avoid dehydration, is also linked to the opportunity of a completely terrestrial life in amniotes. The skin of amniotes may also exhibit typical epidermal appendages such as horny scales, feathers or hair, which share common developmental and evolutionary origins. These appendages diversified into a series of specialized structures and perform several functions including insulation, thermoregulation, sensory perception, camouflage, intra- and interspecific communication, and sexual display.

Although such skin and egg features do not commonly fossilize, skeleton features are useful for identifying fossils as belonging to Amniota. For instance, changes in posture and locomotion in amniotes are reflected in the shape and position of the pectoral and pelvic skeletons. The axial skeleton became regionalized, including distinct thoracic and sacral regions (the latter with at least two vertebra), and a new articulation between the skull and the atlas-axis complex developed. Together with new locomotor strategies and increased mobility of the head, amniotes also

diversified their feeding styles, and this is reflected on the structure of their skull.

New arrangements of the head muscles associated with the diversification of feeding strategies gave rise to distinct patterns of fenestration in the temporal region. Temporal fenestrae are openings in the posterior portion of the skull associated with the passage and attachment of muscles involved in jaw movement. Patterns of skull fenestration have been central to hypotheses of early amniote evolution, and there has been a long debate in the literature regarding their evolution. Despite the different types of temporal fenestration observed among amniotes, recent analyses suggest that only two ancestral types appeared in the early diversification of the group (Ford and Benson 2019). These types of fenestration are associated with a basal split of the crown-group Amniota into two lineages: **Synapsida**, which includes mammals, and **Reptilia**, including reptiles and birds (Figs. 1, 3).

Early tetrapods and reptilomorphs lack fenestrae in their skull, a plesiomorphic anapsid (meaning “without arches”) condition. In Synapsida, a single temporal fenestra is ancestrally present, termed synapsid condition (meaning “single arch”). Therefore, “synapsid” refers both to the type of temporal fenestration and to members of the lineage who ancestrally possess it, with all living synapsids (i.e., mammals) having a modified synapsid condition. In Reptilia, on the other hand, two temporal fenestrae are ancestrally present, a diapsid (“two arches”) condition. Likewise, diapsid refers to members of Reptilia that ancestrally possess this condition, which was also later modified in several different types, including a reversion to an anapsid condition (Ford and Benson 2019).

## Early Synapsids and the Origin of Mammals

Synapsids are characterized by having the temporal fenestration of the synapsid type, i.e., a single temporal opening. The group includes fossil lineages that illustrate the step-wise appearance of many characters typically associated with

mammals, such as the inner ear ossicles. The earliest known synapsids were traditionally referred to as “mammal-like reptiles” because they exhibit plesiomorphic aspects usually associated with reptiles, combined with derived features associated with mammals. Some of these earlier forms were formerly grouped under “Pelycosauria,” a now-recognized paraphyletic assemblage of typically large-sized synapsids. Some of them include famous sail-backed forms. The sail, formed by elongated neural spines putatively supporting a web of skin, probably evolved at least three times among “pelycosaur” groups: in **Ophiacodontidae**, in the strict herbivores **Edaphosauridae**, and in the strict carnivores **Sphenacodontidae** (Fig. 3). The function of the sail is still debated. It was previously linked to thermoregulation, but current consensus is leaning towards sexual display. Early synapsids were abundant from the Late Carboniferous to the Early Permian, and included some of the largest terrestrial animals of the time (e.g., *Edaphosaurus*, *Dimetrodon*), but they are replaced in the fossil record by therapsids in the Middle Permian.

**Therapsida** (Fig. 3) is characterized by an enlarged temporal fenestra, suggesting more developed jaw muscles, and modifications of the postcranial skeleton that, combined with longer limbs, are related to a more erect posture and agile locomotion. They also have enlarged caniniform teeth separating the incisors anteriorly from the post-canine posteriorly. Fossil therapsids include hypercarnivores such as **Gorgonopsia** (Fig. 3), apex terrestrial predators of the Middle and Late Permian, as well as specialized herbivores such as some **Dinocephalia** and the beaked **Dicynodontia**. Early therapsids were the dominant faunal components of terrestrial ecosystems until the Permo-Triassic Mass Extinction, and although a relict “disaster fauna” persisted in the early Mesozoic, they went extinct by the end of the Triassic, when they were ecologically replaced by reptiles.

**Cynodontia** is the clade of more derived therapsids that persisted into the Jurassic. They are characterized by modifications on the skeleton, especially in the skull, that reflect important changes in feeding and breathing. These changes

are linked to a whole remodeling of neural and sensory systems (Rowe 2020), that was fundamental for the diversification of the group and for some of the most distinctive anatomical, physiological, and behavioral features of mammals. Combined with a general trend toward reduced body sizes, these modifications suggest diversification of life habits and ecology among cynodonts.

The development of efficient mastication in fossil cynodonts is evidenced by the appearance of molariform teeth, occlusal facets in dentition, a sagittal crest in the skull associated with muscle attachment, expanded zygomatic arches, and a deep masseteric fossa on the lateral surface of the lower jaw, which suggests hyperdevelopment and rearrangement of jaw muscles, especially the masseter. The secondary palate, a bony plate separating nasal and oral passages, is extensive in cynodonts. Although not unique to synapsids, since crocodiles also have it, in the former it is considered related to mastication. It forms a hard roof against which the tongue can abut to participate in food processing, improving feeding efficiency. The appearance of the secondary palate in cynodonts is accompanied by the development of neural components associated with controlling the muscles involved in the complex jaw movements associated with mastication, and with new sensory possibilities offered by prolonged food processing in the mouth (e.g., orthoretronasal olfaction, Rowe 2020). The development of the secondary palate and posterior displacement of the choanas (internal narial openings) is also linked with the formation and specialization of the nasopharyngeal chamber. The appearance of the chamber resulted in modifications in the olfactory system, and is accompanied by notable developments in the brain regions correlated with the processing of this information in what is considered one of the first pulses of encephalization along the mammalian lineage (Rowe 2020). Finally, further differentiation of the axial skeleton into thoracic and lumbar regions suggests fossil cynodonts used diaphragmatic ventilation. Differentiation of the axial skeleton also enabled wider dorsoventral movements, suggesting synchronism between breathing and locomotion.

Fossil cynodonts more closely related to mammals are united to them in a clade named **Mammaliaformes**. They are noteworthy because they underwent miniaturization during the Mesozoic. With smaller sizes, new habitats and food sources become available, prompting even further the diversification of life habits. Miniaturization involved modifications in the skeleton, resulting in more gracile and agile bodies and boosting diversification of locomotion types. Mammaliaforms have the oldest evidences of fur, and also exhibit larger brains (probably related to the appearance of hair and of endothermy) much more similar to typical mammalian ones (Rowe 2020).

Fossil mammaliaforms also document the gradual transformation of temporal and lower jaw bones that were originally part of the craniomandibular articulation into a series of ossicles involved in sound transmission, the mammalian middle ear bones. In early mammaliaforms, these ossicles are reduced and participate in auditory perception, but are still connected to the posterior portion of the mandible. In postnatal mammals, these ossicles are detached from the lower jaw, which is formed solely by the dentary. The loss of this articulation may have happened independently in monotremes and therians. During this transition to a secondary craniomandibular articulation, both types coexisted: the new one formed by the dentary and the squamosal and related to feeding, and the old one formed by the post-dentary bones of the lower jaw and the quadrate, more suited for sound transmission.

## Extant Mammal Diversity

**Mammalia** originated in the Jurassic, around 170 million years ago. Mammals are characterized by several autapomorphies that include, besides the middle ear bones and the secondary craniomandibular joint, a large brain with a six-layered neocortex, the presence of ethmoid turbinates (a series of elaborate, convolute ossifications in the nasal cavity), and seven cervical ribs fused to their corresponding vertebrae. Mammals

are also distinguished from all other living vertebrates by having external ears and by their namesake feature, the mammary glands, which produce the milk that feeds the newborn.

Mammalia comprises more than 5,800 living species, including humans. Mammals are in general agile endothermic animals. They exhibit several characteristics associated with controlling body temperature, including hair and sweat glands. Ancestrally, they possess a series of differentiated teeth: incisors, canines, premolars, and molars (the latter two characterized by having at least two roots). Dentition is one of the most important characters for identifying mammalian groups, of which the dental formula is an important tool. Mammals explore a vast array of feeding modes that is reflected in a high diversity of teeth numbers, arrangements, and shapes. Mammals also explore different habitats, including fossorial, terrestrial, desertic, aquatic or semiaquatic (including freshwater and marine environments), and aerial. Parental care is an important feature of their reproductive strategies.

**Monotremata** is the basalmost group of living mammals (Fig. 1), with five extant species from Australia and New Guinea, the platypus and echidnas. Monotremes retain the plesiomorphic amniote feature of laying eggs as well as a single opening for the digestive, reproductive, and urinary tracts, the cloaca. Living monotremes do not have teeth, and while echidnas feed on termites and ants using a specialized tongue, the platypus feeds on aquatic invertebrates using a duck-like bill, with a specialized electrosensory system to locate their prey. Monotremes produce milk, but they have no teats; the milk is secreted onto the fur, which their offspring use to help suck the milk.

**Marsupialia** (Marsupialia Morphology, Marsupialia Life History) (Fig. 1) includes opossums, kangaroos, koalas, and others. The name of the group makes reference to the marsupium, a skin pouch located on the abdomen of females of medium and large size species to which embryos migrate in order to complete their development. Although usually considered as an incomplete form of internal development, the marsupium is a very specialized ontogenetic strategy, which

imposes extremely high constraints on their oral and forelimb development. Marsupials and monotremes lack a corpus callosum, which is related to an enhanced communication between parts of the brain, as well as brown adipose tissue, which is related to higher basal metabolic rates. The placenta of marsupials is of the choriovitellinic type, contrasting with the chorioallantoic one of placental mammals. Marsupials are nowadays restricted to Australia and the Americas, where they used to represent apex predators until the arrival of placental mammals, which occurred artificially (by humans) in the former continent and naturally in the latter, with the uprising of the land bridge between North and South America in the Pliocene. The phenomenon of parallelism, or convergent evolution, between marsupial and placental species is well documented in the fossil record of these places.

**Placentalia** (Fig. 1) is currently the dominant mammalian group in terms of species number, including more than 5,000 species in contrast with a few hundred of marsupials. Placentals have a long gestational period and the newborn are more developed than marsupial ones. The understanding of placental interrelationships has been recently revised with the incorporation of molecular data, although most traditional groups proposed based on morphology are still considered valid. Currently, four major clades of placental mammals are generally recognized. **Xenarthra** includes South American groups such as anteaters, sloths, and armadillos. **Afrotheria** includes groups of African origins, like elephants, sea cows, hyraxes, elephant shrews, golden moles, otter shrews, and tenrecs. **Euarchontoglires** is the largest group, with about half the diversity of living mammals. Rodents (► [Rodentia Cognition](#), ► [Rodentia Communication](#), ► [Rodentia Life History](#), ► [Rodentia Navigation](#), ► [Rodentia Sensory Systems](#)) represent most of this diversity, but the group also includes rabbits, tree shrews, colugos, and primates (► [Primates](#), ► [Primate Communication](#), ► [Primate Diet](#), ► [Primate Locomotion](#), ► [Primate Sensory Systems](#), ► [Primate Social Structure](#)). Finally, **Laurasiatheria** includes groups that originated in the former

supercontinent Laurasia, such as hedgehogs, shrews, moles, bats, pangolins, cats, dogs, bears, horses, tapirs, ruminants, hippos, and whales. Despite advances in recent years, there is still much controversy regarding the relationships among these groups, and morphological support for many of these large clades is disputable (Zachos 2020).

## The Other Amniotes: Reptiles

Reptiles are the most diverse group of living tetrapods, with over 20,000 described species (Uetz et al. 2020; Clements et al. 2019). They occupy many niches and have a range of locomotory modes, from flying birds to marine turtles and burrowing snakes. Reptilia is the sister-group of Synapsida (Figs. 1, 3), but many workers use the term “Sauropsida.” However, this is based on the former placement of turtles inside the group, and with their new classification, both terms become redundant (Modesto and Anderson 2004).

Features used to define extant reptiles tend not to include bird characters. They are heavily lizard-based, and often ignore turtle and crocodilian diversity. In fact, they also ignore diversity within lizards. Traditionally, non-avian reptiles possess the body covered in scales, ectothermy and poikilothermy (“cold blood”), retention of the hard-shelled amniotic egg, internal fertilization, and direct development without a larval stage.

Reptiles originated in the end of the Carboniferous (Fig. 1). The most basal members are mesosaurs and parareptiles (Fig. 4), but recent phylogenetic analyses have challenged this traditional view, and “lepospondyls” like rhynchonkids and lysorophians have been recovered as basal groups (Pardo et al. 2017b), as well as some varanopid synapsids (Ford and Benson 2019).

**Mesosauria** is a group of aquatic reptiles with several adaptations to aquatic habitats such as thickening (pachyostosis) of ribs, long caudal neural spines for support of the caudal fin, and a long snout with long and thin teeth for fish feeding. Mesosaurs inhabited a shallow inland sea between southern South America and Africa

during the Early Permian. The presence of mesosaur fossils on both continents was one piece of evidence supporting the continental drift hypothesis. **Parareptilia** was the first reptile group specialized for herbivory. Some parareptiles show convergent features with later reptiles such as skull fenestration, erect posture and tympanic hearing.

**Diapsida** represents the largest reptile radiation and includes all the living representatives of Reptilia (Fig. 4). Turtles used to be one exception, as they were considered parareptiles. Birds were the other, but are now included among theropod dinosaurs. Besides all extant reptiles, Diapsida also includes several fossil radiations, such as the tree-dwelling and digging drepanosaurs, the gliding weigeltisaurids, and aquatic reptiles. They are characterized by two skull fenestrations, besides relatively elongate distal bones of the forelimbs, and an elongate fourth metatarsus (a toe bone).

## Aquatic Reptiles

Together, marine reptiles constitute an important reptile ecomorph. Not only were they abundant during the Mesozoic, but they also represent the first major tetrapod expansion to open waters. Marine reptiles were the dominant predators in pelagic environments by the Middle Triassic; lamnid sharks did not begin to occupy these niches until the Cretaceous (Condamine et al. 2019). One reason for the underappreciated success of marine reptiles is that it is unclear whether some of the most successful lineages (ichthyosaurs and sauropterygians) form a monophyletic group and where they fit in the reptile tree. Their specialized anatomy, coupled with the lack of transitional fossils from their terrestrial ancestors, is to blame.

The expansion into pelagic environments was gradual and the most derived marine reptiles developed a lifestyle completely removed from land, including limbs transformed into flippers and live birth. Anatomical convergence with present-day aquatic vertebrates, especially between dolphins and ichthyosaurs, are common

**Vertebrates (Chordata), Fig. 4** Cladogram with the phylogenetic relationships of Reptilia. Groups with exclusively fossil representatives are shown in gray. Some clades are named at the nodes

textbook examples of convergence (► [Convergent Evolution](#)) and selective pressure regarding the evolution of flippers and of hydrodynamic body forms.

Early **Ichthyopterygia** (Fig. 4) had an elongate body and tail, contrasting with later ones with shorter tails and reduced hind limbs. An anoxic event in the early Late Cretaceous is believed to have led to the extinction of the group. Ichthyosaurs became extinct before the famous

Cretaceous-Paleogene (K-Pg) extinction event. Plesiosaurs are the most recognizable member of **Sauropterygia** (Fig. 4). They had broad and flat bodies, flippers, a reduced tail, and one lineage, the elasmosaurs, evolved very long necks. Plesiosaur limbs were well-developed, indicating that they were involved in locomotion, in contrast with ichthyosaurs, that used primarily tail fin propulsion. Sauropterygians had elevated metabolic rates and are considered mesotherms. Finally,

**Choristodera** is a group with an oddly flattened and elongated skull. Choristoderes had an extended time range of occurrence time range, from the Late Jurassic to the Early Miocene. Their phylogenetic position, however, indicates they must have existed since the Middle or Late Triassic. Other fossil aquatic reptiles are known, but they belong to the crown-group and will be dealt with later.

## Lepidosaurs: The Classic Reptiles

Lepidosaurs constitute the most diverse reptile group, together with birds. Their lineage originated in the end-Permian (Fig. 1), but their fossil record is very scarce until the Late Triassic. Of the two lepidosaur clades, **Rhynchocephalia** is currently represented by only one living species, the tuatara of New Zealand (Fig. 4). Despite this very low extant diversity, rhynchocephalians are the most abundant group in the early fossil record of lepidosaurs, representing their first radiation. They are known for a characteristic type of tooth implantation called acrodonty, in which the teeth sit atop the jaw bone, in contrast to the sockets of mammals and crocodylians (thecodonty) and the open groove of most lizards (pleurodonty). Several lizards convergently developed an acrodont dentition, so that the tuatara condition is not unique among reptiles. Rhynchocephalians also have the ancestral condition of the reptile skull in which the lower temporal fenestra is closed ventrally by a bar. Fossil rhynchocephalians include ecologically important radiations, like the aquatic group **Pleuroosauridae** and the herbivorous **Opisthodontia**, as well as the widely-distributed clade **Clevoosauridae**.

The other lepidosaur clade, **Squamata** (► [Squamate Sensory Systems](#), ► [Squamate Cognition](#), ► [Squamata Diet](#), ► [Squamate Life History](#)), includes lizards and snakes (Fig. 4). They are considered generally primitive and homogeneous. This, however, enormously underestimates squamate anatomical (► [Squamate Morphology](#)), physiological, and ecological diversity. With development of molecular methods, the

taxonomic diversity of squamates increased considerably and the phylogenetic relationship among major clades mostly settled, although controversies persist. Living squamates are characterized by having keratinized scales, but they have lost osteoderms, dermal bone elements present in many tetrapods, including extant crocodylians and armadillos. They are mostly oviparous, but several instances of internal development with a placenta are known.

Squamates are regarded as “cold blooded,” a category that usually mixes up concepts of ectothermy and poikilothermy. The first refers to an external source of heat, while the latter describes changes in body temperature. Their opposite, endothermy and homeothermy, are found in birds and mammals, although variations within these groups exist. Several squamates keep their body temperature constant throughout the day by behavioral mechanisms, or through gigantism. Similarly, seasonal reproductive endothermy has been recognized in **Teiidae** (Tattersall et al. 2016). Squamates occupy several ecological niches, including fossorial, arboreal, gliding, semiaquatic, and marine groups. They are found in all regions except the arctic and antarctic ones. One recurrent evolutionary trend in the group is the loss of limbs. Not only snakes are limbless, but several lizard groups have also lost or drastically reduced their limbs. Skull mobility is another classically recognized trait, taken to an extreme condition in snakes.

Among the main squamate groups are **Dibamidae** and **Amphisbaenia**, entirely fossorial groups. Like caecilians, they exhibit a compact skull used for burrowing, with the fusion of skull bones and reduction or loss of the eyes. **Gekkota** represents a mostly nocturnal radiation while **Serpentes** is the most diverse squamate group with over 3,700 species. Important fossil radiations of squamates include **Paramacellodidae** and **Borioteiioidea** during the Mesozoic.

Snakes are known for their limblessness, extremely elongate body, highly mobile skulls through the loss of the upper temporal bar and rearrangement of the craniomandibular articulation, and the presence of venom, although only one quarter of the species are known to be

venomous. The origin of snakes is one of the most heated debates in squamate phylogeny. Snakes originated around the Middle Jurassic, but the fossil record is scarce until the Late Cretaceous. The highly modified snake skull and the complete loss of limbs makes it difficult to determine which is their sister group. Because some of the earliest fossils are found in marine sediments, snakes have been hypothesized to be the sister group of **Mosasauria**, a clade of aquatic Mesozoic reptiles. The concurring hypothesis suggests snakes originated from burrowing lizards, and that their closest related group is **Varanidae** (Garberoglio et al. 2019).

## Archosauria

Archosauria is another large clade of living reptiles. The lineage originated in the end-Permian, but unlike lepidosaurs, their early fossil record is very rich. Several anatomical archosaur features are considered key innovations for their Mesozoic radiation, including the antorbital fenestra, thecodont tooth implantation, erect posture, and the fourth trochanter of the femur. These features are related to enhanced locomotion and increased metabolic rates. Groups outside the bird-crocodylian devise display a plethora of niches including aquatic clades like **Tanystropheidae** and **Proterochampsia**, herbivorous groups such as **Rhynchosauria** and **Trilophosauria**, as well as hypercarnivorous (► **Carnivore (Diet)**) taxa like **Proterosuchidae** and **Erythrosuchidae**.

The transition from sprawling forms to more agile, cursorial predators happened relatively fast and was further developed independently in the two archosaur groups, **Pseudosuchia** (crocodile line) and **Avemetatarsalia** (bird line) (Fig. 4). Until the Late Triassic, pseudosuchian fossils were more abundant, indicating their predominance during early archosaur evolution. In the end of the Triassic and beginning of the Jurassic, there is a drastic fall in their taxonomic and morphological diversity and a general increase in avemetatarsalians, especially dinosaurs. What caused this decrease is unknown, but competition between them has been suggested.

Triassic pseudosuchians include **Phytosauria**, crocodile-like aquatic animals with retracted nares on the top of the skull, like dolphins. **Aetosauria** represents heavily armored herbivores with an upturned snout for excavating the soil. **Ornithosuchidae**, **Poposauroidae**, and **Rauisuchidae** are hypercarnivorous groups with deep skulls. The morphological diversity of pseudosuchians during the Triassic was later mirrored by several dinosaur groups in the Cretaceous.

Whatever the cause of their decline in the end-Triassic, the aquatic environment seems to have been a refuge for pseudosuchians. During the Jurassic, most of the pseudosuchian fossil record is aquatic – although it should be noted that fossiliferous terrestrial deposits from the Jurassic are scarcer than aquatic ones. They include **Thalattosuchia**, with some species adapted to the pelagic environment, with flippers and caudal fin. Terrestrial pseudosuchians are represented during the Jurassic by small, slender forms collectively known as “sphenosuchians,” which is now considered paraphyletic. The terrestrial diversity did not flourish until the Cretaceous, but was extinguished soon thereafter. It is represented by **Notosuchia**, an anatomically diverse group highly abundant in Gondwana, where the fossil record of theropod dinosaurs is very poor (Fig. 4). Notosuchians have an array of dental morphologies, evidencing varied feeding strategies with hypercarnivorous and herbivorous taxa, but also grinding types with molariform-like teeth similar to mammals.

The current diversity of pseudosuchians is restricted to around 30 **Crocodylia** (► **Crocodylia Communication**) species only (Figs. 1, 4). They are all semiaquatic and carnivorous (► **Crocodylia Diet**), have internal fertilization, and lay hard-shelled eggs. Crocodylians were traditionally regarded as big lizards, but their morphology (► **Crocodylia Morphology**) and physiology are more like the ones of birds, including a four-chambered heart. This has led some to hypothesize that crocodylians are secondarily plesiomorphic in many traits, i.e., their primitive-looking characters correspond in fact to loss of derived features, like endothermy

(Seymour et al. 2004). The circulatory system in crocodylians changes from when they are on land to when they are diving (apnea). In these cases, crocodylians can perform a “cardiac arrest,” in which the lung loop of the blood flow is closed and the blood runs through the heart only (Kardong 2012).

## Dinosaurs and the Origin of Birds

One of the most basal groups in the bird lineage is **Pterosauria** (Fig. 4). Pterosaurs took into the air long before birds, and some have suggested that their niche competition made it difficult for pterosaurs to survive the K-Pg mass extinction event. They coexisted in some places, however, where birds occupied more closed environments and pterosaurs were found in open habitats such as lakes and shorelines.

The pterosaur wings are unlike those of birds in that they use a membrane stretched between their over-developed fourth finger and the sides of their bodies (their fifth digit is lost). Pterosaurs ranged greatly in size, from wingspans of around 1 m to over 10 m wide. They were quadrupedal on land, and capable of active flight on air. Like birds, pterosaurs had lightly-built, hollow bones and a system of air sacs. The delicate structure of their skeleton may account for the difficulty in reconstructing the transition from a terrestrial ancestor. Pterosaurs possessed well-developed cerebral hemispheres and semicircular canal systems in their inner ears, which may have been related to flight. Their bodies were covered in thin, feather-like structures called pycnofibers. Some species displayed strong ► **sexual dimorphism**, exhibiting tall crests on their skulls and snouts, and their fossils are often found in groups, suggesting gregarious habits.

**Dinosauria** is the most popular group of extinct animals (Fig. 4). They originated in the Middle Triassic and dominated terrestrial ecosystems until the end of the Mesozoic, with only one clade, birds, surviving the K-Pg boundary. The first dinosaurs were small, facultative quadrupeds and likely possessed feather-like structures like the pycnofibers of pterosaurs. Dinosaurs are

classically classified in three groups: ornithischians, sauropodomorphs, and theropods, which includes birds.

► **Ornithischia** is a group that includes mostly herbivorous and quadrupedal dinosaurs, although bipedal and facultative bipedal species exist, as well as ► **omnivore** taxa (Fig. 4). Two iconic ornithischian clades include **Stegosauria**, with plates along their back (e.g., *Stegosaurus*), and **Ceratopsia**, with their characteristic skull frills and horns (e.g., *Triceratops*). Ceratopsians were high-fiber mega-herbivores whose specializations included teeth batteries, dental occlusion, and high rates of tooth replacement. Specializations for herbivory also include their “bird-like pelvis”, from which the name “Ornithischia” is derived. The reversed pubis better accommodates increased gut lengths, facilitating fermentation. In contrast, in derived theropods and birds, the reversed pubis is related to their highly cursorial habits and increased metabolism. Another famous ornithischian group is **Hadrosauria**, which includes duck-billed dinosaurs with cranial crests. Hadrosaurs were highly specialized herbivores, having evolved several grinding features similar to mammals. Ornithischians in general are well known for their gregarious habits and parental care (► **Parental Investment**).

**Sauropoda** (or Sauropodomorpha) (Figs. 1, 4) is also an herbivorous group, but unlike ornithischians, their specializations are based on niche partitions, such as browsing versus grazing, and stratified heights. Sauropods are famous for their extremely long necks and large body sizes. In fact, sauropods feature among the largest animals known to have ever existed, although insular dwarfism is known in the group. Several aspects related to their gigantism remain largely unknown, including the evolutionary and ecological processes that prompted this trend, such as sexual selection and resource availability. Sauropods, like birds, possessed an air sac system in the neck vertebrae, which may indicate a unidirectional airflow during breathing and, consequently, highly efficient ways of oxygen intake. Similar to ornithischians, sauropods are also known for their herding habits and for a high level of parental care.

Finally, **Theropoda** (Fig. 4) is the group of bipedal dinosaurs that includes the most famous fossil of all times, *Tyrannosaurus rex*. Some theropod groups independently achieved large body sizes, such as **Megalosauroidae**, **Allosauroidae**, and **Tyrannosauroidae**. Theropods in general were specialized for fast bipedal stances, losing two to three digits on their hindlimbs, and some groups also have their forelimb size and digit number reduced. These were, however, internal trends, since in successive groups closer to birds forelimbs proportionally increased in size, probably in association with the origin of flight. Although mostly carnivorous, some theropods were omnivorous and herbivorous, such as **Ornithomimosauria**, **Therizinosauria**, and **Oviraptorosauria**.

Several trends are observed in successive sister-groups of birds associated to the development of flight. For instance, the theropod brain increased in size, especially the optic lobe and cerebral hemispheres, which are responsible for processing complex visual information. Physiological modifications include the further development of the air sacs, which is part of the breathing system, implying in increased metabolic rates. Feathers were present in most, if not all, theropod groups. They become more specialized and differentiated into several types, such as down or flight feathers. Osteological modifications include fusion of forelimb bones and wrist adaptations to stand lift, decrease in density of bones, and overall reduction in body size. Although birds are known for flying, they are not the only theropods to have done so. Groups closely related to birds were also capable of flying, sometimes engaging in their own evolutionary novelties, such as the four-winged group **Microraptor** and the weird, bat-like group **Scansoriopterygidae**. All non-avian clades became extinct following the K-Pg boundary.

## Birds

Birds comprise the most speciose of the classic terrestrial vertebrate groups, together with lizards

and snakes, accounting for nearly 11,000 species (Clements et al. 2019). Among extant vertebrates, birds are easily recognized by the presence of feathers, beak, and wings, and are mostly associated with their ability to fly. However, bird flight was a process that started long before the origin of the group and that continued long thereafter.

Bird characters that appeared before the group were listed in the previous section. Among the ones acquired after the origin of the group is the beak, as early birds still had teeth. The beak is formed by truncation of the anterior region of the skull and by elongation and fusion of the premaxillae. In fact, the bird beak might be as important as flight for their diversity, but much of the underlying processes involving its appearance is still unknown. Early birds also possessed long tails, which become gradually shorter and whose vertebrae eventually fuse, forming the pygostyle. The development of the carina in the sternum is also important, which evidences the role of the flight muscles in generating lift. It is worth noticing that some of these features, like the loss of teeth and the appearance of a pygostyle, may have been homoplastic.

Birds appeared during the Late Jurassic (Fig. 1) and became very diverse by the Cretaceous, when the crown group **Neornithes** originated (Figs. 1, 4). However, following the K-Pg mass extinction, bird fossils are rare, contrasting with molecular analyses which show that birds went through a rapid radiation following the K-Pg. Recent findings indicate that the likely reason for the low number of fossils is the small size and delicate nature of the avian skeleton. Important Mesozoic radiations include groups like the diverse and globally distributed **Enantiornithes** and the aquatic clade **Hesperornithes** (Fig. 4). Both retained teeth, and derived hesperornitheans had vestigial wings and specialized hind-limbs for foot-propelled diving.

Most of the current diversity of birds is represented by songbirds, which account for 60% of their diversity (Clements et al. 2019). The peak of bird diversification and the origin of passerine birds coincides with the Eocene Thermal Maximum, when many groups were globally widespread. Sound communication is

very characteristic for birds, which is taken to an extreme by songbirds, with the development of a specialized organ in the airways, the syrinx. Special muscles in this region can produce sound in a continuous manner, even when air is flowing into their respiratory system. Birds are unique among tetrapods in that they have a unidirectional airflow in their lungs, which maximizes the oxygen outtake from the air in a counter-current fashion. Bird behavior is also remarkable, and of all reptiles, they show the most elaborate forms of courtship and parental care.

The earliest bird lineage to diverge was **Palaeognathae**. It is comprised of mostly flightless birds (ostrich, rheas, emus, cassowaries and kiwis) referred to as ratites. The exceptions are the flying tinamous of Central and South Americas. Palaeognaths receive this name from their craniopalate articulation, which is common also in other reptiles, but has been lost in other birds. Some of the largest birds to have existed are paleognaths, namely, the moa of New Zealand and the elephant bird from Madagascar. The current distribution of ratites over former Gondwanan landmasses was used as example in vicariance models in the early days of ► [biogeography](#). However, to be found in places like Madagascar, ratites would have to have diverged prior to the breakup of Gondwana, in the Early Cretaceous. Fossil and molecular data shows that their divergence was much more recent, suggesting that dispersal involved a flying ancestral and that cursoriality evolved multiple times independently in this lineage.

All other birds, who lost the reptilian craniopalate articulation, are classified in **Neognathae**. The earliest-diverging group includes **Anseriformes** (ducks and geese) and **Galliformes** (chicken and pheasants), both of which are economically and culturally important for humans. Some anseriforms have genitalia so elaborate they commonly feature among examples of sexual conflict. Anseriforms represent an important aquatic radiation, with some species having serrated beaks and tongues for filter-feeding. Fossil anseriforms are represented by terror-bird-like taxa from the Gastornithidae and Dromornithidae families. Like other terror birds,

these used to be considered giant predatory birds, but this is now contested. Galliforms are well-known for game birds, many of which show strong sexual dimorphism with elaborate caruncles in their heads, vivid colors, extravagant tails, and intricate behaviors. For that reason, and for some extreme cases like peacocks, they usually are textbook examples about ► [sexual selection](#).

The remaining groups of birds form the group **Neoaves**. The phylogenetic relationships among them are controversial, but recent molecular analyses are settling the debate. It includes pigeons and doves (**Columbiformes**), nocturnal clades (**Strisores** and **Strigiformes**), birds of prey (**Accipitriformes** and **Falconiformes**), an aquatic group (**Aequorlithornithes**), songbirds (**Passeriformes**), and others.

### **Testudines (► [Testudines Cognition](#), ► [Testudines Life History](#), ► [Testudines Navigation](#))**

The placement of turtles in the evolutionary history of reptiles is still controversial. Turtles were considered pareiasaurian parareptiles, which was at the time further reinforced by the lack of apparent fenestrations in their skull. Like with Synapsida and Diapsida, “Anapsida” was used for the group including turtles, but it now refers only to the skull condition. Molecular studies first placed turtles on the lizard lineage, but recently they have been recovered in the archosaur line, outside the bird-crocodile split (Figs. 1, 4). Recent fossil discoveries of turtles without a fully formed shell have corroborated the archosaur hypothesis. Therefore, the anapsid condition of turtles is currently regarded derived from a diapsid skull, and the emarginations on the top of the skull have been reinterpreted as modified upper temporal fenestrae. Turtles appeared in the Middle Triassic (Fig. 1) and were not very diverse throughout their history. Turtle richness peaked in Europe during the Early Cretaceous, declining after the K-Pg, but a global pattern for diversification or extinction is absent.

Turtles have a very distinctive body plan, with a characteristic shell composed of two adjoined

parts, a plastron in the belly and a carapace in the back. The first known fossils were already fully formed turtles with a plastron and a carapace, which made it difficult to place them in the reptile tree. The discovery of fossils with a plastron but underdeveloped carapace, in addition to developmental studies, elucidated some of the process of shell formation (Lyson and Bever 2020). Shell development is connected to a less known fact about turtle anatomy (► [Testudines Morphology](#)), that their shoulders lie inside their ribcage, with some elements fused to the plastron. While some reptile groups show structures similar to shells, like pareiasaurian parareptiles and placodont sauropterygians, in none of them, nor in any other vertebrate known, the internalization of the shoulder girdle occurs.

Much of the internal turtle anatomy is modified due to the presence of the shell, the organs being accommodated in the restricted space of a rigid rib cage that will not expand. The most remarkable modification is in the respiratory system, with the development of a unique leverage system through which muscle contraction presses the viscera against the carapace to expel air, while return to the original position results in inhalation (Lyson and Bever 2020). Turtle hearts have three chambers, but unlike those of lepidosaurs, the ventricle is subdivided by a prominent muscular ridge, resulting in a functional four-chambered heart (Kardong 2012). Like crocodilians, turtles can deviate the blood flow when they dive. Turtles lack teeth and have a queratinous beak covering their jaw bones, which can be serrated.

Turtle fossil radiations outside the crown include **Meiolaniidae**, a long-lived family that inhabited Australia and New Caledonia until about 10,000 years ago, and **Thalassochelydia**, a group of Late Jurassic European sea turtles. Crown turtles are divided in **Pleurodira** and **Cryptodira**, with the main anatomical difference being their strategy for neck retraction. Pleurodirans put their necks to the side, in a space between the plastron and the carapace, while cryptodirans retract their necks fully inside their shells. Stem turtles had no mechanism for neck retraction. Pleurodirans also have their

pelvic girdle fused to the carapace, like their shoulder girdle.

All living pleurodirans are semiaquatic, freshwater animals, but the fossil record includes some marine species in the family **Bothremydidae**. This group was one of the most globally distributed, together with the living family **Chelidae**. Currently, pleurodirans are mostly restricted to the Southern Hemisphere. In contrast, living cryptodirans are much more diverse and found in all environments, from freshwater, to marine, to terrestrial. The most diverse group is **Testudinoidea** and the least but most iconic one is that of sea turtles, **Chelonioidea**, with only seven species. Chelonioids are the only pelagic group of sea turtles, with limbs transformed into flippers, although they still rely on terrestrial environments for laying eggs. Fossil chelonioids from the family **Protostegidae** include some of the largest turtles known. Testudinoid families include the tortoises (**Testudinidae**), which are mostly terrestrial, and **Geoemydidae**, most of which are aquatic and semiaquatic, with webbed digits.

## Definition

Anatomical structure that has lost its original function in a species during the course of evolution.

## Introduction

Vestigial organs are rudimentary anatomical structures that are retained in a species despite having lost their primary ancestral function. These structures often lack an apparent purpose, in contrast to the full functionality of these organs observed in closely related and ancestral species. The term “vestigial” was first utilized by Wiedersheim (1895) for use in the context of rudimentary structures that serve no apparent function. Archetypal examples of vestigial organs include structures such as wings in nonflighted birds, eyes in blind species, and vestigial limbs in snakes. Organs often become vestigial when selection for their original function becomes relaxed. They range from disadvantageous to selectively neutral to slightly advantageous (Gould 1980). Vestigial organs may be more variable compared to the same structure in other

species and may appear degenerated. Related terms such as exaptations and spandrels (discussed in detail below) are often confused with vestigial organs but are separate concepts.

## History

The observation of vestigial structures in living organisms was first described by Aristotle, in his fourth century BC book, *History of Animals* (Aristotle, c. 350 BC). Aristotle described vestigiality in the eyes of *Spalax typhlus*, a blind mole rat. He noted that although the mole rat can scarcely see, it still has eye structures that have been “stunted in development” (Aristotle, c. 350 BC, Part 9). This ancient Greek description provides evidence of an early interest in the unique characteristics of vestigial structures and their purpose in living organisms.

In the eighteenth and nineteenth centuries, vestigial structures continued to be a major point of interest in biological and evolutionary studies. In 1809, French naturalist and evolutionary theorist Jean-Baptiste Lamarck described the presence of vestigial, nonfunctional structures in many animals in his work, *Philosophie zoologique* (Lamarck 1809). His interpretation of the development of vestigial structures, also known as Lamarck’s “First Law,” described how a change in the environment also changes the needs of the organisms living in that environment. This, in turn, leads to changes in their behavior. This altered behavior subsequently leads to a greater or lesser use and utility of a given structure or organ. Increased use would cause the structure to increase in size within an individual and increasingly across generations, whereas disuse would cause it to shrink or even disappear (Lamarck 1809).

The idea of anatomical structures changing over time in response to environmental changes was elaborated and refined by Charles Darwin later in the nineteenth century (Darwin 1859, 1871). In Darwin’s seminal book, *On the Origin of Species*, he described the vestigial eyes of moles and cave-dwelling animals as “probably due to gradual reduction from disuse, but aided

perhaps by natural selection” (Darwin 1859, p. 137). In a later work in 1871, *The Descent of Man, and Selection in Relation to Sex*, Darwin described examples of “rudimentary organs” in many species and related their evolution “use and disuse” in his work (Darwin 1871). This idea of “use and disuse” incorporates some elements of Lamarck’s “First Law,” but Lamarck believed that reductions in anatomical structures would occur initially at the level of the individual. Darwin expanded on Lamarck’s hypotheses to include the impact of natural selection compounding the effects of vestigialization across generations.

With a focus on the evolutionary history of human anatomy, Robert Wiedersheim described 86 human organs considered to be “vestigial” in his work, *The Structure of Man* (Wiedersheim 1895). In it he wrote, “comparative morphology points not only to the essentially similar plan of organization of the bodies of all vertebrates, . . . but also to the occurrence of them in certain organs, or parts of organs, now known as ‘vestigial’ by such organs are meant those which were formerly of greater physiological significance than at present.” (Wiedersheim 1895, p. 2). This list of human vestigial organs is similar to those described by Darwin (1871) and includes anatomical structures that are known today to serve an essential function in human physiology. An example listed by Wiedersheim as a vestigial organ is the vermiform or cecal appendix. However, recent research (described in more detail below) provides evidence against vestigiality of the cecal appendix.

## Evolutionary Processes

The word “vestigial” is derived from the Latin word “vestigium,” meaning a trace, mark, or track. As such, vestigial structures are considered traces of past evolutionary processes. Vestigial organs can provide insight into previous evolutionary pressures, because they represent identifiable traces of ancestral characteristics or behaviors in living organisms (summarized in Müller 2002). These evolutionary changes shed

light onto the adaptations of past generations and reveal how adaptive pressures may have shifted compared to earlier members of the phylogenetic lineage.

Vestigial structures typically arise when positive selection pressures for the original function become reduced, often due to changing environmental conditions or novel adaptations. Over time, relaxed adaptive constraints may render the structure more susceptible to the impacts of neutral evolutionary process such as mutation and genetic drift, which produce greater variability in the vestigial organ (Gould 1980). This process also often results in a reduction in size of the vestigial organ, such that the organ becomes atrophied or underdeveloped. The vestigial organ may also appear only during early stages of development and be lost in adults, such as gills in the embryos of air-breathing land vertebrates. Sometimes, the vestigial organ may cause no direct damage to the organism but may still require maintenance or developmental costs, causing it to be slowly phased out. In the most extreme cases, the structure may even be selected against if its function or presence becomes detrimental to the organism's success under the changing circumstances.

One example of the aforementioned vestigial atrophy phenomenon is the auricular (ear) musculature that moves the ear of mammals with large mobile ears, such as monkeys. There is strong selection for well-developed auricular muscles in monkeys because they serve a significant survival function by providing an improved ability to hear potential predators and other hazards (Macalister 1871). Since humans have primarily stationary ears, selection on these auricular muscles has relaxed, and they have consequently become degenerated (Darwin 1871). While ear muscles are still present in modern humans, they are diminutive, and most people possess only minimal voluntary ear mobility.

In humans, there are several examples of vestigial structures including but not limited to wisdom teeth (third molars), ear muscles, and various small tendinous muscles. One specific structure to note, the palmaris longus muscle, is absent in approximately 14% of the population

and provides no additional grip strength (Sebastin et al. 2005). This muscle is considered vestigial due to its lack of serious forearm muscle action, as well as its variability among humans and other close primate relatives. In fact, the palmaris longus provides so little functional efficacy to wrist movement, that it is commonly harvested and used as surgical tendon graft material for other parts of the body where tendons or ligaments are needed, such as anterior cruciate ligament (ACL) repairs. Patients with removed palmaris longus tendons do not show any reduction in grip strength in its absence (Sebastin et al. 2005).

Another classic example of vestigial structures can be observed in the pelvic anatomy of certain snakes. Some primitive snakes have pelvic spurs, which are vestigial remnants of legs found in either side of the vent (Pough et al. 2003). Two well-known examples of snakes with pelvic spurs are boas and pythons. These remnants of the pelvis and femur simply float within the pelvic muscle mass on either side of the snake's cloaca. The rudimentary vestigial femur also protrudes from the snake's body, resembling a spur or a claw. It is believed that these structures may now serve a purpose in the mating behaviors of these snakes (Pough et al. 2003). If this is the case, they could be considered examples of exaptation.

## Identification of Vestigial Organs

Vestigial organs are generally identified through comparisons of related species. Evolutionary patterns are evaluated in structures that are believed to be homologous, or shared due to common ancestry. For example, wings in all extant (modern) birds are the result of descent from a shared common ancestor with wings. Since the primary function of wings in most birds is to fly, the primary adaptive function of wings is interpreted to be flight. In birds that cannot fly, such as the ostrich, the presence of wings is therefore considered vestigial, because the ostrich's wings have lost their original adaptive function compared to other closely related avian species.

The process of identifying vestigial organs may rely upon tracing the evolution of a structure across a phylogenetic tree of genetic relationships. This process is often referred to as phylogenetic bracketing (Witmer 1995). Following this approach, characters are mapped onto a phylogenetic tree. An organ is inferred to be vestigial in a species if it seemingly lacks a function compared to an apparently functional state in at least two other closely related species (Witmer 1995). This analysis indicates whether the organ has lost its function in comparison to its relatives, which would qualify it as vestigial.

Identifying a vestigial organ can sometimes be challenging because the process requires confirming that the structure under question no longer serves its original adaptive function. These identifications can be difficult if the original function of an organ is unclear or unknown, such as structures that appear only in the fossil record with no modern analogue. In these cases, experimentation may shed light onto the possible functions of these ancient structures.

## Exaptation

As early as Darwin's time, it was noted that some organs, while providing a seemingly useful function, may serve a purpose other than their original adaptive function (Darwin 1859). For example, Darwin noted that sutures in the skulls of infant mammals facilitated the birthing process. However, the skulls of developing reptiles and birds also have sutures, so it would not be accurate to suggest that sutures evolved as an adaptation to parturition (Darwin 1859). Similarly, in his landmark text on adaptation, George C. Williams noted that some organs serve "effects" that should be considered separate from their original adaptation (Williams 1966). However, despite observations regarding the nuances of adaptive and vestigial characters, a term was not proposed to describe evolutionarily co-opted structures until the 1980s.

Exaptation is a distinct, though related concept to vestigiality. Exaptation occurs when an organ loses its original function but takes on a new adaptive purpose (Gould and Vrba 1982). The

structure is useful to the organism and offers a selective advantage, despite having lost its initial functionality. In other words, an exaptation is a structure that is co-opted for a new, adaptive use (Gould and Vrba 1982). Because the exaptation still has an adaptive value to the species, it cannot be considered truly vestigial.

Since an exaptation is commandeered for a secondary purpose, it may be an imperfect design for the new function (Bock 1959). Evolution in the case of exaptations has been argued to play the role of a "tinkerer" rather than an engineer, working with existing parts to modify and make them fit a certain function rather than starting with an ideal design plan from the outset (Jacob 1977). The classic example of this phenomenon is the panda's "thumb," which is not composed of phalangeal bones but instead of an expansion of the radial sesamoid, making it comparatively clumsy compared to fully phalangeal primate thumbs (Gould 1980).

There are several examples of exaptation in avian (bird) evolution. First, feathers likely first evolved for thermoregulatory purposes in flightless avian dinosaurs (Sumida and Brochu 2002). After they appeared, feathers were later co-opted for flight, which is highly adaptive and beneficial to the success of bird species. Second, wings in aquatic birds such as penguins are another classic example of an exaptation. While the structure of wings initially evolved to facilitate flight, these wings have been co-opted for propulsive swimming in aquatic birds. Therefore, since both feathers and wings serve clearly adaptive purposes in modern birds that differ from their original adaptive purpose, they are considered exaptations.

A recent example of exaptation is the cecal "vermiform" appendix in humans and other mammals (Bollinger et al. 2007; Smith et al. 2013, 2017). Scholars have long noted that human survival is not negatively impacted by the removal of the appendix, suggesting to many that it served no adaptive function. Charles Darwin originally hypothesized that the appendix in humans and other great apes is a vestigial organ because its purpose was unknown at that time (Darwin 1859). Darwin hypothesized that as an outpocketing of the gastrointestinal tract, the appendix must have

once served a digestive function. However, the large intestine decreased in size in frugivorous (fruit-eating) ape ancestors, resulting in an appendix that is too small to serve any digestive function (Darwin 1859). However, it was noted by early twentieth century medical practitioners that the appendix contained a concentration of lymphoid tissue, a type of support tissue for the immune system (Berry 1900). Only in the last decade has the functionality of the appendix become apparent, reversing the idea that it is a vestigial organ. In 2007, Randall Bollinger and colleagues described a biofilm of beneficial gut bacteria in the appendix, which led them to hypothesize that the appendix serves an important function in maintaining commensal gut microflora (Bollinger et al. 2007). Comparative analyses mapping appendix evolution on the mammalian phylogenetic tree have revealed that the appendix evolved multiple times throughout mammalian evolution, suggesting that it serves an adaptive function. Thus, taxa with an appendix have a higher concentration of lymphoid tissue in the appendix/cecal region, supporting its immunological role (Smith et al. 2013, 2017).

## Spandrels

Another concept that is important to differentiate from vestigial organs are structures that are referred to in the evolutionary biology literature as “spandrels” (Gould and Lewontin 1979). A spandrel was originally an architectural term, referring to the triangular space between two contiguous arches and the ceiling. However, in their seminal work, *The spandrels of San Marcos*, Steven Jay Gould and Richard Lewontin (1979) made the analogy between architectural spandrels at Saint Mark’s cathedral and certain anatomical features. Architectural spandrels are simply the byproduct of two adjacent arches, but they are often decorated in ornate Renaissance style. Therefore, an architectural novice might presume that the function of spandrels was to showcase beautiful artwork, while in reality they are merely the result of the geometry of arches.

Similarly, some anatomical structures, they argued, may appear to have evolved for a

particular purpose when they were actually simply the result of an unrelated evolutionary event (Gould and Lewontin 1979). In other words, evolutionary spandrels are features that arise as byproducts, rather than through adaptation and selective pressures on the structure itself. The occurrence of evolutionary spandrels cautions biologists from interpreting every anatomical structure as either adaptive or vestigial and serves as an important reminder that the evolution of some structures may result from selective pressures and adaptive changes that only indirectly shaped the organ. A spandrel could also be considered a type of exaptation if it serves an adaptive function in the species.

## Conclusion

Vestigial organs are generally defined as structures having lost their original evolutionary function. Such structures can provide insight into former evolutionary pressures and behaviors and indicate how adaptive regimes have shifted across a phylogenetic lineage through time. However, the identification of vestigial structures is marred by the fact that evolution is resourceful. Even anatomical structures whose original function becomes lost may still be selected for alternative purposes, as in exaptations. In addition, some structures that appear vestigial are actually evolutionary byproducts that never served a function at all, as in spandrels. Thus, upon review of many structures that are considered classic examples of vestigiality, it becomes apparent that truly vestigial organs are quite rare. From wings used for swimming in nonflighted birds to the immunological functions of the vermiform appendix and the panda’s “thumb,” evolution is flexible and offers creative solutions to adaptive problems.

## View-Based Homing

Paul Graham<sup>1</sup> and Antoine Wystrach<sup>2</sup>

<sup>1</sup>School of Life Sciences, University of Sussex, Brighton, UK

<sup>2</sup>Research Center on Animal Cognition (CRCA), Center for Integrative Biology (CBI); CNRS, University Paul Sabatier, Toulouse, France

In one of the most famous animal behavior studies of all time, Niko Tinbergen mischievously disturbed the day-to-day navigation of a solitary wasp. While the wasp was inside her burrow, he placed a ring of pine cones around the entrance, and upon leaving she noticed the change, flew a series of inspection loops, and departed. Upon returning from her trip, the wasp searched for the nest at the center of the ring of pine cones even though the ring had been displaced (Tinbergen and Kruyt 1938). These experiments revealed that the wasp did not detect the nest entrance directly, but knew its location because of the relationship with the visual surroundings. With another animal anecdote, we can show a similar phenomenon. Karl von Frisch, who shared the Nobel Prize with Tinbergen, observed a bird building a nest in the repetitive eave structure of

a bike shed (von Frisch and von Frisch 1974). Evidently using the remembered appearance of the bike shed roof to pinpoint the nest location, the bird made multiple mistakes because so many potential nest locations looked the same. The result was rather energy sapping for the poor bird, with multiple nests being built in parallel. These two examples show how remembering the appearance of the world from a target location can be used to guide behavior. This is a general mechanism called view-based navigation. It works because in a complex natural world, unlike von Frisch's bike shed, views are specific to locations. For example, two photographs taken with the same camera can only be identical when the camera location and orientation are matched. This relationship between views and locations means that remembered views can be used to home to a specific discrete location or to set a direction of travel, two actions which are general requirements of animal navigation.

There are fundamental reasons why view-based matching is a sensible, efficient strategy for any navigator. Different animals have different sensory systems and different ways of perceiving the world (their *Umwelt* or self-world), resulting from filters developed during their evolutionary and personal history (von Uexküll 1957). However, for animals with any type of visual system, view-based matching is a computationally inexpensive process because the visual information perceived can be used directly for navigation. Views are necessarily perceived from an egocentric point of view (i.e., depending on the animal's current position and direction), and with view-based matching, views can be memorized and compared directly within this egocentric frame of reference, without the need to be transformed into more complex spatial representation. In addition, egocentric views are an excellent task specific representation of the world because views change with movements. Movements in space (i.e., navigational behavior) map simply onto changes in the position of visual components of a view; therefore, differences between current views and remembered views can be transformed into corrective movements. Furthermore,

robustness comes from the informational content of natural visual scenes. A remembered view will contain information from multiple objects of different sizes and distances. This means that views change smoothly as one moves and these smooth changes allow animals (or robots) to calculate the required movements to recover an orientation, return to the location of a remembered view, and to detect when one has arrived.

Following Tinbergen and more detailed experiments with bees (Cartwright and Collett 1983), the use of egocentric remembered views for navigation is often thought of as a simple insect strategy, often referred to as snapshot matching. However, all animals have to deal with egocentric views (i.e., their sensory input) and we know that these views can directly provide effective and economical solutions for navigation. Therefore, it is no surprise to see convergent use of egocentric views for spatial tasks across taxa, such as in birds and mammals, including humans (Wang and Spelke 2002; Shelton and McNamara 2004; Pecchia et al. 2011). We also see similarities in the way that animals use multiple remembered views to guide idiosyncratic habitual routes (Kohler and Wehner 2005; Biro et al. 2004; Calhoun 1962; Hartley et al. 2003) which seems to be a convergent strategy for moving through familiar environments, as humans typically do when recapitulating a well-known route on "autopilot."

For robust view-based navigation, what matters is the spatial arrangement of the objects across the scene, and not the identification of those objects. Interestingly, object and spatial memories seem to be dissociated in vertebrate brains. For example, human patients with visual agnosia following brain damage are often unable to recognize objects, even though they can navigate through the world (Farah 1990). In contrast, spatial navigation can be strongly impaired when lesions occur in the parahippocampal place area (PPA), a region involved in scene recognition, based on wide-field information about the layout of objects (Epstein 2008).

It is clear that animals differ in the way they perceive and use visual information. Insects may

rely entirely on egocentric views for navigation, while we humans can recognize individual objects and build more complex spatial representations. However, for certain tasks, such as repeated navigation through familiar environments, views are an efficient and computationally inexpensive strategy. For large brained animals, this may reserve valuable cognitive resources for other tasks. Therefore, we caution that in no case should we assume that the existence of more complex spatial abilities in some animals precludes the convergent use of simple, robust strategies across taxa (Wystrach and Graham 2012).

## Vigilance

Gisela Kaplan

School of Science and Technology, University of New England, Armidale, NSW, Australia

Vigilance involves basic information gathering (Bekoff 1995). It is the active act of deliberate watchfulness and monitoring of potential threats caused by predators and even conspecifics. Heightened vigilance in animals is usually based on specific environmental circumstances, such as a noise or a movement that may warrant careful assessment. Heightened vigilance may also be indicated if an environment is unfamiliar and/or if visibility is poor and could potentially hide an ambush predator. Vigilance is associated more with prey species than with predators; at least the need for vigilance may be ongoing in prey species but be rare or intermittent among predators unless a competitor is nearby. In addition, vigilance is associated with the protection of nest sites (Yasukawa et al. 1992) and dens (Santema and Clutton-Brock 2013) (Figs. 1 and 2).

Having to be vigilant can have a number of negative side effects, chief of which is the

**Vigilance,**

**Fig. 1** Vigilance including scanning can be readily measured in mammals as well as in birds – such as extending neck, turning head, and the angle of the turns. **(a)** Australian magpie scanning the sky, turning head to left in order to scan the sky with the right eye; **(b)** meerkat having detected a potential predator raises its head and turns it to the right, facing upward. Credit: Gisela Kaplan

**Vigilance, Fig. 2** Sentinels usually choose the highest vantage point, be that on a small hill as in prairie dogs or meerkats or at the very highest point of a tree, here a yellow-tailed black-cockatoo on sentinel duty while the rest of the family feeds lower in the tree. Credit: Gisela Kaplan

inability to forage simultaneously while scanning the environment. This applies particularly to some mammals with frontally placed eyes. Birds can scan for predators in the lateral monocular field while pecking at food items in the frontal field, but this limited viewing is often not sufficient. A number of species solve this problem by flocking together or at least increasing group size, as is

the case in ungulates (Han et al. 2020) and in shorebirds (Metcalf 1984). Other group-living species share sentinel duties (Wright et al. 2001) allowing the rest of the group to forage and increase biomass (Hollén et al. 2008).

Vigilance behavior, specifically in prey species and in environments with high predator presence, is also related to fear. Indeed, threats are part of what has been termed “a landscape of fear.” It has been shown in countless studies that these “fear effects” can significantly alter the physiology, behavior, and life history of prey species (Gallagher et al. 2017). Fear can have sublethal effects on prey behavior and physiology and may have long-term consequences for prey population dynamics. Boonstra et al. (1998) showed in snowshoe hares that vigilance only served to confirm high predation risk and induced chronic stress which led to a series of health effects, such as loss of weight, stunted growth, cessation of reproductive activity, and eventually death by predation.

However, associating vigilance with fear may be problematic, as Beauchamp (2019) pointed out. Some animals experience fear without showing vigilance, and some may become desensitized to threats because they are too hungry.

There is a third reason to not automatically associate vigilance with fear, and this has to do

with experience and learned strategies of what to do in facing or avoiding danger. In Australian magpies, for instance, vigilance behavior is highly developed, ranging from periodically flying to the top of trees, scanning at high vantage points as well as at any other height and on the ground. If a predatory intruder is identified, alarm calls bring the territorial group together which then proceeds systematically and effectively to drive that predator out (Koboroff et al. 2013), even if it is substantially larger than they are, such as wedge-tailed eagles (Kaplan 2019). They have learned to outsmart potential predators. When cooperation is involved and/or past experience and an understanding of the predator's strategies and weaknesses, stress levels tend to be low or return to normal very quickly, and vigilance in these cases is part of a well-prepared method to remain in control regardless of a predator's size and strength.

### ► Benefits for Aggression in Humans

## Virtual Reality Experiments

Tina Peckmezian

Macquarie University, Sydney, NSW, Australia

## Synonyms

Computer interface; Computer-generated environment; Simulation

## Definition

In the context of experimental research, virtual reality refers to immersive, computer-generated environments that are sensed by the subject and are updated by the subject's actions in real time.

## Introduction

Virtual reality (VR) technologies are increasingly used in the behavioral sciences to overcome the constraints of traditional “open-loop” experiments. Open-loop experimental designs decouple sensory stimuli from motor behavior by

presenting stimulus conditions to the subject independently of the subject's responses to these stimuli. In contrast, closed-loop (feedback) systems such as VR allow stimulus conditions to be updated by the subject's responses in real time.

Since VR experiments are typically implemented using automated, computer-controlled technologies, virtual stimuli and virtual environments can be designed along a spectrum from abstract to photo-real and can include parameters and contingencies that would otherwise be impossible to create in the real world. As such, VR can provide a valuable middle ground between ecological validity, in which the "realness" of the experimental design is paramount, and experimental control, in which experimental variables are highly reliable and precisely controlled (Bohil et al. 2011).

### Components and Considerations

Recent advances in technology have enabled the development of a number of different VR systems for experimentation with animals. In general, a VR system should comprise the following components and considerations:

1. *Generation and display of the virtual environment:* The VR system must be carefully designed to reflect the sensory system properties of the test species. For a visually based system (the most common focus of VR presently), chromatic, luminance, and spatial properties of the animal's entire visual system must be taken into account. For example, for animals with very wide fields of view (such as mice, flies, and zebrafish), panoramic, hemispherical, or spherical displays may be most appropriate. Another important consideration is the selection of a display screen with an appropriate critical flicker-fusion frequency (CFF) in relation to the CFF of the experimental animal. The CFF is the frequency at which a flickering stimulus begins to appear continuous and varies widely between taxa. For example, slow-moving animals such as crickets have CFFs in the range of 45 Hz, while fast-moving animals such as bees have very high CFFs in the range of 300 Hz. To ensure that screen flicker is not detectable in the visual display, the CFF of the visual stimuli should be equal to or greater than the CFF of the experimental animal. For a more detailed discussion of the challenges of using video stimuli in behavioral experiments, see D'Eath (1998).
2. *Restraint:* While restraint is not requisite for VR (for example, see #3 below, regarding servomotor-based systems), restraining the interacting animal allows for simultaneous recording of behavior and neural activity. Restraint is commonly performed by immobilizing the head and allowing some or all of the rest of the body to move normally. For example, head-fixed monkeys can perform a virtual navigation task while hippocampal cells are recorded (Hori et al. 2005); head-fixed drosophila continue to fly by beating their wings in a flight arena while electrophysiological recordings are conducted (van Swinderen 2012); and head-fixed jumping spiders mounted atop an air-supported spherical treadmill can navigate through a 3D virtual environment (Peckmezian and Taylor 2015; see Fig. 1).
3. *Recording movement:* Motion tracking is a critical component of both freely moving and tethered VR systems. Early free movement systems used servomotors to control the rotation of a sphere that an animal was freely walking on, with movements detected by rotary encoders that were in direct contact with the sphere. Subsequent versions have positioned tethered animals atop spherical treadmills supported by a cushion of air, with spherical rotations detected by optical or laser computer mice positioned nearby. Most recently, a vision-based tracking system has been designed that overcomes many of the constraints of computer mice (such as sensitivity to changes in illumination, texture, and radial and diagonal motion) by motion tracking the rotations of an air-supported sphere using an off-the-shelf webcam (Moore et al. 2014).
4. *System latency:* Across all sensory modalities, the latency for the simulation to update is a critical feature of a virtual reality system and is intricately linked with the perceived "realness" or level of immersion in the simulation.

**Virtual Reality Experiments, Fig. 1** Example of VR implementation for experiments with jumping spiders (see Peckmezian and Taylor 2015). (a) Schematic of VR system. Spiders are mounted above an air-supported spherical treadmill placed inside a hemispherical display screen. Dynamic computer generated 3D environments are front-projected onto the screen via a pocket projector with add-on fisheye lens, and spider movements are detected by a camera-based tracking system (FicTrac) and update the

world in real time (a closed-loop system). (b) A spider mounted above a spherical treadmill in preparation for a trial. A magnet is fixed to the spider's dorsal carapace and a magnetic pin holds the spider in position. (c) A close-up of a jumping spider with magnetic cap in place. The cap can remain in place to minimize handling between sessions or can easily be removed with tweezers. (d) An example of a virtual prey object (available through *Biometric games*) and a simple, virtual arena (constructed in Unity 3D).

Long delays between an animal's movement and a corresponding update in the display can break the feedback loop that defines a closed-loop system. The total VR system latency is based largely on three components: tracking, rendering, and display. In general, the update latency should be equal to or less than the animal's corresponding reaction time.

### Benefits of Virtual Reality Experiments

Virtual reality experiments offer a number of advantages over traditional methods in behavioral research. First, VR allows the subject to interact naturalistically with the simulated environment. Compared with open-loop computer-based experimental designs, VR allows researchers to present and control multimodal stimulus inputs, so that the subject experiences a greater degree of

sensorimotor immersion. It is not necessary for the stimuli present in a virtual environment to perfectly match the real world along all domains; rather, the goal of virtual design is to replicate a sufficiently convincing subset of the features that the subject would sense while moving freely within the real equivalent of the virtual environment (Dombeck and Reiser 2012).

Second, VR equips researchers with intricate control of a multitude of experimental parameters, including both those presented to and recorded from the subject. The researcher can present combinations of stimuli that are not found in the real world and can enact changes in the environment that would not be possible physically. Likewise, VR allows the creation of landscapes that are greatly extended from what would be feasible in a typical space-constrained lab.

And third, when paired with restraint, VR provides a powerful context in which to couple

behavioral and perceptual experiments with neurophysiological recordings. In tethered flies alone, techniques such as whole cell patch clamp, extracellular recordings, and functional two photon microscopy have been used to record from visual neurons and interneurons during visual motion stimulation (reviewed in Dombeck and Reiser 2012).

### Limitations and Common Criticisms of Virtual Reality

While significant advances in the technologies supporting VR have occurred in the past decade, immersive VR systems are still relatively costly and challenging to execute. To build a visually based VR system, for example, specialized skills are required in programming, 3D modeling, stimulus design and animation, and projection and tracking softwares.

In addition, providing an adequate level of realism to elicit “normal” behavioral (and neurophysiological) responses poses numerous technological challenges. In restrained animal preparations, one such hurdle is the lack of appropriate motion cues. Most mammals (including commonly studied taxa such as humans, primates, and rodents) have a vestibular system within their inner ears that contributes to spatial orientation, movement, and balance. A lack of appropriate vestibular input in animals interacting in virtual environments can confound both electrophysiological recordings and the subjects’ experience of immersion. For example, restrained rats and primates navigating in virtual environments display hippocampal place cell activity that is markedly different than when they navigate in the real world (primates: Hori et al. 2005; rodents: Hölscher et al. 2005). Similar behavioral artifacts can be observed in restrained invertebrate species that possess equilibrium sensors. Flies, for example, exhibit distortions in flight behavior when mechanosensory feedback from specialized stabilizing organs, the gyroscopic halteres, is impeded, as is the case during restraint. The limitations imposed by equilibrium sensors can be circumvented through VR studies of walking invertebrates that lack equilibrium sensing organs, such as spiders, by avoiding restraint altogether with free-movement systems,

or by adequately accounting for these effects in experimental design and/or interpretation.

### Conclusion

VR is emerging as a powerful tool in the study of animal behavior and neurophysiology, with unique advantages over other experimental approaches. Recent technological advances in many of the components of virtual systems have improved the fidelity, realism, and applicability of these systems to a wide range of animal models and experimental paradigms. While most current VR systems emphasize visual stimuli, virtual environments delivering olfactory, auditory, or tactile cues broaden the range of animal models available to VR experimentation and, when paired with visual cues, are likely to increase the realism of the simulation.

## Visible Characteristics

### ► Phenotype

---

## Visible Displacement

Rebecca Singer  
Georgetown College, Georgetown, KY, USA

## Synonyms

[Object permanence](#)

## Definition

Visible displacement is the ability to locate a hidden object after seeing that object placed in, under, or behind an occluder.

## Introduction

Visible displacement is one stage of developing object permanence. Object permanence is the understanding that objects exist even when they not able to be directly perceived. Piaget (1954) proposed that human children develop object permanence during the sensorimotor period of development. Further, object permanence skill developed slowly in six stages. In the first stage,

human infants show no response to the disappearance of an object. Infants in stage 2 will track an object of interest but will not follow the object once it is out of sight. Further, they show no anticipation of where the object would logically be once it moves out of sight. By stage 3, children can locate partially hidden objects such as a toy that is sticking out from under a blanket. Children will successfully retrieve fully hidden objects in stage 4. This is called visible displacement. However, children make a consistent error in stage 4. The A-not-B error means that children will look in a location that an object was repeatedly hidden even though, this time, they witnessed the toy being hidden in a different location. By the fifth stage, children have grown out of this error and are capable of finding an object where it was the most recently hidden. The sixth, and final, stage of object permanence development involves seeing an object hidden under a displacement device and then moved to a new hiding location. The object is surreptitiously placed in the new location and the empty displacement device is shown to the child. This is called invisible displacement. Children who have mastered stage 6 object permanence are able to track the movement of the hidden object and correctly locate it in the new location.

## Experimental Methods

The methodology for testing visible displacement in human infants on object permanence tasks is well established. In the traditional method of testing for visible displacement, a child is shown a favorite toy and then the toy is hidden underneath a blanket or other occluder (Piaget 1954). The child with object permanence would lift up or reach under the blanket to retrieve the hidden toy. An alternative test would be to place the object inside one of three boxes and then ask the child in which box the toy is located. Children with object permanence successfully choose the box with the hidden toy inside.

An alternative method is the violation of expectation test. In this type of experiment, a

child watches an event take place, but the ending is changed in such a way as to violate what the child expects to see. One simple test of this is to show a child a toy and then place it behind a barrier. The barrier can then be rotated either 120° or 180°. The 120° rotation would be an expected event because the barrier should not be able to rotate through an object placed behind it. The 180° rotation would be an unexpected outcome because, if an object is placed behind the barrier, the barrier should not be able to rotate through the hidden object (Baillargeon et al. 1985). One application of the violation of expectation procedure was to demonstrate that human children were able to solve visible displacement tasks at an earlier age than was proposed by Piaget. While Piaget suggested that children did not develop object permanence ability until approximately 12–18 months of age, several studies using the violation of expectation procedure have demonstrated that infants as young as 3.5 months of age demonstrate visible displacement (Baillargeon and DeVos 1991).

## Visible Displacement in Animals

Visible displacement tests in animals typically take the form of asking whether animals can identify which of several occluders a hidden object is in. Many animals have been tested and pass visible displacement tests including dogs, cats, parrots, and many monkey species (see Jaakkola et al. 2010 for review). Ape species such as chimpanzees and orangutans also successfully pass these visible displacement tests (e.g., Call 2001).

Jaakkola et al. (2010) demonstrated that bottlenose dolphins are successful at visible displacement tasks as well. In this experiment, dolphins were asked to indicate in which of three opaque containers a toy had been placed. Similar results were reported by Mitchell and Hoban's (2010). Here, the trainer held the object (a fish) directly over one of the containers and dropped it in on some trials or picked up a bowl and put the fish in it before placing the bowl back in the water on other trials.

More recently, the violation of expectation (VOE) testing method has been used to test Atlantic bottlenose dolphins and California sea lions on visible displacement. In this experiment, Singer and Henderson (2015) used the animal's fish bucket as the object. The animal was shown the fish bucket and then it was placed on a table. A research assistant rotated a screen either 120° or 180°. Experimenters recorded mean looking time for both trials types. Looking times were significantly longer on surprise trials (180°) than on expected trials (120°).

## Limitations

Recently, research has focused on addressing the limitations of many of these prior studies. The primary concern is that animal may have been able to choose the correct location of a hidden object by using associative rules. For example, an animal may associate the container that was last touched with the object rather than relying on mental representation of where the hidden object is (Collier-Baker et al. 2004). The location of the experimenter, eye gaze or body position of the experimenter, or trajectory of the object may all lead to associative learning (Andras et al. 2016). The violation of expectation effect methodology may be one way to control for associative learning, but research with appropriate controls is also being called for.

## Conclusion

Most animals tested on visible displacement are successful at tracking an object as it is hidden. Future studies focus on ruling out associative learning explanations for these successes.

## Visual Cliff, The

Joy Vincent  
Oakland University, Rochester, MI, USA

## Definition

The visual cliff is an apparatus designed by Eleanor Gibson and Richard Walk (1960) to study the development of depth perception in a variety of species. The main structure is a glass board that is suspended in the air; a checkered-patterned fabric is placed flush against one side of the glass and another piece of the same fabric is placed on the ground below the other side of the board. This creates the visual illusion of a cliff. The subject is placed on a center board between the two sides, and the choice behavior of which side they descend to is recorded. This apparatus has been used to study a variety of concepts, including the development of depth perception, stimulus cues used in depth discrimination, and the importance of locomotion and rearing environment.

## Introduction

The visual cliff was a methodological marvel at the time of its conception in the mid-1900s. Created by Eleanor Gibson and Richard Walk (1960), this relatively simple apparatus allowed for the systematic examination of depth perception. It quickly became a popular tool in developmental psychology for testing the presumption that depth perception is innate (Rodkey 2015). Despite earlier attempts to tackle this question, it cannot be disputed that the design of the visual cliff provided more valid results than preceding methodologies. This innovative solution presented subjects with a semi-natural problem that required no training and minimal experimenter interference.

The actual design of the apparatus is relatively simple and, after some early alterations, it has not required many revisions since its conception (Rodkey 2015). To create the visual illusion, a single piece of glass is supported above the ground, and a piece of checkered material is placed flush against one half of the glass board. This gives that half (known as the shallow side) the appearance of solid ground. On the other side of the glass (known as the deep side), the same checkered material is placed on the ground, giving the appearance of a cliff. Subjects were placed on a center board that was situated between the two sides and their behaviors were recorded (Walk and Gibson 1961). Rodkey (2010) suggested that the quintessential innovation of this apparatus was that it relied solely on preference, rather than jumping and physical aptitude – as was the case in previous studies.

The design of the apparatus, specifically the use of checkered patterns, allowed researchers to manipulate specific cues necessary to discriminate depth, including relative texture size and density, motion parallax, and flow pattern (Bradley and Shea 1977). This has given researchers the freedom to manipulate various features in the environment to get a more complete understanding of the development of depth perception. Gibson and Walk (1960) also conducted a series of control studies early on to determine if there was an effect

of the lighting reflecting on the glass of the deep side. The results were not significantly different when they changed the lighting location, suggesting that any reflections were not affecting the subjects' behavior.

In general, when placed on the center board of the apparatus, individuals of a variety of taxa demonstrated a clear preference for the shallow side of the apparatus, suggesting that they experience the perception of depth (Eichengreen et al. 1966; Gibson and Walk 1960). Further results that focused on the development of this sense suggest that there may be an important element of experience in an individual's depth perception, beyond their developmental stage (Bradley and Shea 1977; Tees 1974).

## History of the Visual Cliff

When the visual cliff hit the academic marketplace, so to speak, it took the field of psychology by storm. Throughout the 1960s and 1970s, visual depth perception received a great deal of attention with significant research coming out on a variety of taxa (reviewed in Rodkey 2015). This methodology has taken hold in the mythos of psychology, quickly becoming a staple in introduction to psychology textbooks. There are, however, a number of misconceptions about the origins of the visual cliff and its chief objective.

It has often been suggested that the visual cliff was designed to address the prevalent nature versus nurture debate at the time (Rodkey 2010). This post hoc determination can be traced back to the results of visual cliff studies that support the assertion that visual experience is not a necessary precursor to animals avoiding the deep side. Although these results have been championed to support the nativist perspective in the ongoing debate, Gibson and Walk have intentionally attempted to abstain from the discussion. They have even gone so far as to deny any links between the inception of the visual cliff as a methodology and nature versus nurture debate (Rodkey 2015).

Another tall tale that has similarly been enmeshed in the visual cliff's history is Gibson's inspiration. As the story goes, while Gibson and her family were visiting the Grand Canyon, she observed her infant child stopping at the edge of the cliff and looking over, and this is what gave her the inspiration to create the apparatus (Rodkey 2015). While this makes for a sensational story, it is simply an inaccurate recreation of what truly happened. The idea to study depth perception came from a 1934 study, wherein Lashley and Russell attempted to study depth perception by looking at the force at which rats jumped from one platform to another. Their idea was that rats should adjust the force they use to jump based on the perceived distance between the take-off location and the landing location. They further expanded on this work by studying differences in rats that were raised with light and those that were raised in darkness to examine whether visual experience impacted depth perception. They concluded that depth perception was innate in rats. These results, however, came under scrutiny because the rats had to be trained to jump and this training had to be conducted in the light (Tees 1974). This flaw cast doubt on the findings because the alleged "visually inexperienced" rats did have some level of visual experience prior to the study.

The visual cliff was designed in the spur of the moment when Gibson was given access to a number of dark reared rats. She decided to put together a rudimentary version of the visual cliff with items already in the lab (Gibson and Walk 1960). By virtue of the cliff's design, it did not require training and thus, could sidestep the methodological issues of Lashley and Russell's study. The apparatus also facilitated testing of a variety of other species, including goats, dogs, cats, humans, and a host of other taxa. Nearly all species tested, from the time that they could independently move about their environment, demonstrated an immediate aversion to the deep side of the apparatus. Nearly all deviations in this pattern have been explained in terms of differences in rearing environment, neural damage, or species' ecology.

Three primary versions of the visual cliff led to the version that we know today (reviewed in

Rodkey 2015). The Cliff Model I was the original design; it was relatively rudimentary, requiring rods and clamps to hold it above the ground and had no protective edges to keep the subjects safe. The Cliff Model II was the result of necessary modifications, and resembles the design commonly found in textbooks. This model was a wood box that was suspended from the ceiling. The final alterations to Cliff Model III were simply to increase its size to accommodate larger subjects, such as goats and infants.

Human infants have certainly been one of the most studied subjects on the visual cliff with studies encompassing visual depth perception and numerous developmental milestones. However, as outlined previously, the first subjects of the visual cliff were rats, followed by a series of other species that were studied prior to human infants (Gibson and Walk 1960). Since Gibson and Walk first published their work on the visual cliff in 1960, a host of species have been studied, including chicks, cats, dogs, goats, sheep, pigs, rabbits, lions, tigers, jaguars, snow leopards, monkeys, and other rodents (Gibson and Walk 1960; Rosenblum and Cross 1963; Routtenberg and Glickman 1964; Thiessen et al. 1968), with all of them showing a preference for the shallow side.

## Stimulus Cues

Given the wide array of taxa that have overwhelmingly chosen to descend to the shallow side of the cliff, the question arises as to the precise mechanism driving this preference. Scientists also wanted to learn about the cues and mechanisms used in discriminating depth. There are two proposed mechanisms for how individuals compute the depth of the different surfaces and, in turn, how they use that information to avoid the deep side (Green et al. 1993). One is that the individual may compute the absolute distances of all the surfaces around them and avoid any surface that is beyond an acceptable vertical distance below them. In the visual cliff, the deep side would be beyond that acceptable vertical distance, resulting in the subject choosing to descend onto the shallow side, which falls

within an acceptable distance. The other proposed mechanism is that they may compute the relative distances between adjacent surfaces and avoid any surface where the vertical distance increases rapidly with the horizontal distance. In the visual cliff, the vertical distance on the deep side increases dramatically compared to the center board, whereas the shallow side has a very small increase in vertical distance from the center boards, resulting in the subject choosing the shallow side. In other words, individuals can either attend to absolute or relative cues when discerning depth and making choices about their environment.

The visual cliff has proven itself equally useful in learning about the specific cues that are central to an individual's depth perception. The patterned fabric in the design of the visual cliff allowed for scientists to examine the impact of relative pattern size on side preference. To test this, patterned fabric was placed flush against both sides of the apparatus, differing only in the size of the checkered pattern. Gibson and Walk (1960) found that rats showed a preference for the larger checkered pattern, postulating that this was due to the larger pattern being more reminiscent of "closeness." Despite these results, this preference does not seem to be innate. A similar procedure with visually inexperienced day-old chicks showed no preference for side; however, over subsequent trials, subjects developed a preference for the shallow side (Gibson and Walk 1960). In contrast, similarly reared chicks, when placed in the apparatus with the sides set up as normal, immediately demonstrated the expected preference for the shallow side. This suggests that pattern-size alone is not a sufficient explanation for how animals discriminate depth cues.

An alternative explanation is that motion parallax may serve as an innate cue for depth, whereas using the cue of pattern size may be learned. Motion parallax is the speed at which stimuli move across one's field of vision. Applying this concept to the visual cliff, as an individual moves their head, pattern elements on the shallow side will appear to move more rapidly across their field of vision than elements on the deep side (Gibson and Walk 1960). Gibson and Walk

(1960) attempted to parse out the importance of motion parallax in depth perception by increasing the size and spacing of the pattern on the deep to be perceptually identical to the pattern on the shallow side from the center board. This made motion parallax the only perceptual difference, which was sufficient for nearly all infant rat and day-old chick subjects to consistently choose to descend to the shallow side. This suggests that motion parallax likely serves as an innate cue for depth.

## The Importance of Locomotion

The visual cliff has been most commonly linked with developmental psychology, rather than with comparative psychology, despite the menagerie of species that have been studied (Rodkey 2015). This is likely because the early studies with human infants yielded important results regarding the development of the visual system at different developmental milestones. Specifically, Gibson and Walk (1960) focused on the importance of independent locomotion in the development of depth perception. They observed 27 babies that had reached the crawling stage and found all but 3 of them descended to the shallow side. This pattern has also been seen in a variety of other taxa. Rats showed the expected behavior of descending to the shallow side at 16–17 days of age, which is about 2 days after opening their eyes (Bauer 1973). Likewise, chicks consistently demonstrated the expected pattern of behavior after less than 24 h of hatching (Gibson and Walk 1960). Each of these time frames correspond with normal locomotion development in each species.

These observations supported the premise that depth perception develops along a similar time frame to locomotion. This led Gibson and Walk (1960) to make the broad conclusion that, in sighted animals, the ability to perceive and discriminate depth develops with independent locomotion, even in species whose locomotion starts at birth. The underlying logic of this conclusion is that depth perception should be adaptive for individuals that are moving about their environment

independent of external forces, as it provides a level of protection against traversing dangerous areas (e.g., cliffs).

## The Importance of Environment

Above and beyond being used to study the general development of visual depth perception and the associated cues used to discriminate depth, the visual cliff has also been employed to study how neurological and environmental factors can impact the development of this visual process (Rodkey 2015; Tees 1974). One of the most common variations harkens back to the original visual cliff study, wherein Gibson and Walk (1960) explored the question of whether depth perception was innate by studying the behavior of rats reared in a dark environment. Since their original studies, the visual cliff has also been used to study learning processes and the different impacts of rearing environment.

Tees (1974) took a longitudinal approach with his study, examining the rate at which dark-reared versus light-reared rats discriminated between the deep and shallow sides. He found that those raised in the dark were slower to acquire the discrimination and actually showed a deterioration in their abilities after 100 days, whereas light-reared rats instead showed a rapid acquisition and gradual asymptote in performance after 100 days. Tees (1974) proposed two important functions on visual experience in the development of depth perception. The first is that visual experience allows the individual to hone their ability to make accurate depth discriminations. The second is that the visual experience jump-starts neural structures that are central to the ability. He suggests that the deterioration in performance of the dark-reared individuals is evidence for the lack of development of these underlying neural networks.

Support for Tees's assertion for the importance of underlying neural structures can be found in previous studies that examined the impact of neocortical lesions on performance on the visual cliff (e.g., Hebb 1963). Meyer et al. (1966) found that rats with lesions to their visual neocortex showed

no preference for the shallow side and performed similarly to the control animals that had been fully blinded. When testing cats, however, they found that those with lesions still avoided the deep side. The researchers suggested that this result may be more prudently attributed to methodological difference in the post-surgery environments of the two species. This possibility hints at the importance of environment in the development of depth perception.

Early studies tended to focus on the importance of visual experience, through the application of light versus dark rearing environments. In years since, there has been a shift in focus to other environmental features that may play important developmental roles. In particular, researchers have focused on the importance of enriched environments. Bradley and Shea (1977) examined how gerbils that were raised in a topographically complex environment compared to those raised in a flat environment performed on the visual cliff. They found that, while 21-day-old gerbils did not show an immediate preference for the shallow side of the apparatus, those raised in the enriched environment developed the expected preference in under 48 h whereas those in the flat environment did not develop the preference until they were 60–61-days-old.

Their explanation of the results is based on the idea that gerbils have the capacity to discriminate depth, but they require experience with the environmental features in order to utilize the capacity (Bradley and Shea 1977). An alternative explanation is that both groups of gerbils were able to discriminate the depth, but those in the flat environment group did not have the requisite fear response to the visual cliff (Wilson and Risen 1966). Those reared in the enriched environment, on the other hand, had experience with the dangers associated with cliffs and thus could rapidly learn to avoid the deep side of the apparatus. Both explanations are based on the underlying logic that an individual's experience with an enriched environment, wherein they gain experience with features that necessitate the use of depth perception, may better equip them to make educated decisions on the visual cliff.

## Ecological Considerations

Nearly every species that has been tested on the visual cliff has demonstrated a preference for the shallow side of the apparatus (Gibson and Walk 1960; Rosenblum and Cross 1963; Routtenberg and Glickman 1964; Thiessen et al. 1968). That is to say, nearly every terrestrial species. The most notable exceptions to this “rule” are sea turtles and ducks (Gibson and Walk 1960). Sea turtles deviated the most from the expected pattern with nearly 24% of subjects descending to the deep side. One suggestion is that they have poorer depth perception than other species tested. A more widely accepted hypothesis, however, is that it does not align with their natural ecologies (Gibson and Walk 1960). The visual cliff works by virtue of the fear animals have for falling; because they do not want to fall off a cliff, they avoid the deep side. This fear of falling does not occur in sea turtles, as falling off a cliff is not an ecologically valid concern in their environment. When turtles swim over the wall (the ocean’s equivalent of a cliff) they do not “fall.”

In contrast to the lack of fear in turtles, Gibson and Walk (1960) made a number of amusing observations concerning fear of the deep end in their early studies. When animals, such as lambs and goats, were placed on the glass over the deep side they demonstrated stereotyped fear responses, despite the tactile assurance of the glass. They would go into defensive behaviors, refuse to put their feet down, and would be unable to motivate themselves to move toward the “safety” of the shallow side. These reactions, along with the divergence in expected preference of the sea turtle, are all in line with the behaviors that would be expected from the animals in the wild. The ability to discriminate depth is incredibly important to the survival of most terrestrial species, which is why its development is so closely tied to that of independent locomotion.

## Conclusions

The visual cliff took the psychology world by storm when it was first introduced by Gibson

and Walk in 1960. Since its conception, it has been used to study a multitude of developmental and perceptual concepts. It presented researchers with a semi-natural problem that required no previous training. Through the use of this apparatus, researchers have been able to study a plethora of species. They have consistently found that species perform according to what is known about their life histories and ecologies, most commonly preferring the shallow side of the apparatus. The visual cliff has similarly been used to study the stimuli that control depth discrimination, as well as the impact that a rearing environment has on the development of depth perception. Although incredibly simple in design, the visual cliff has been revolutionary in the realm of psychology and has lent to an incredible amount of knowledge in the fields of comparative and developmental psychology.

## Visual Detection Task

Emma K. Stewart  
University of Western Ontario, London, ON,  
Canada

### Definition

A series of trials in which an observer must recognize the presence or absence of a visual stimulus or feature of a stimulus.

## Introduction

A visual detection task is a task in which an observer must recognize the presence or absence of a visual stimulus or feature of a stimulus. This could include the presence of a faint stimulus (e.g., light), movement, or a specific image (e.g., face) among spatially or temporally adjacent distractor images. Signal detection theory describes how target stimuli are discriminated from patterns of non-target information (referred to as noise). This is based on features such as the intensity of the stimulus and the noise in the background or detection system (e.g., perceptual system) of the observer. Making a selection generally involves selecting a threshold based on the noise and signal + noise distributions and then deciding whether the stimulus falls above or below the threshold. Signal detection theory was first described by researchers studying radar detection (Peterson et al. 1954), who determined, mathematically, the behavior of an “ideal” observer. This concept was applied to visual detection in human observers by Tanner and Swets (1954) and later by Green and Swets (1966). There are four possible outcomes when an observer attempts to detect the presence or absence of a signal (Fig. 1). The sensitivity index ( $d'$ ) is commonly used as a performance measure; however, different assessments may be used depending on the detection model. The sensitivity index represents the difference between the means of the signal + noise and noise distributions in terms of the standard deviation of the noise distribution (Tanner and Swets 1954). This was later modified for cases in which the variances of the noise and signal distributions are unequal ( $d_a$ ; Fig. 2).

## Assessing Visual Detection

Visual detection can be studied through examining behavioral outcomes or neural responses. It is commonly measured through accuracy and reaction times of behavioral responses. In psychophysics, the accuracy outcomes form a psychometric curve, which maps the relationship between stimulus intensity and percentage of correct responses using a sigmoid function.

|                  | Respond "Absent"  | Respond "Present" |
|------------------|-------------------|-------------------|
| Stimulus Present | Miss              | Hit               |
| Stimulus Absent  | Correct Rejection | False Alarm       |

**Visual Detection Task, Fig. 1** The possible outcomes of a detection task in which stimuli are either present or absent

$$d' = Z(\text{hit rate}) - Z(\text{false alarm rate})$$

$$d' = \frac{\mu_S - \mu_N}{\sigma_N} \quad \text{OR} \quad d_a = \frac{\mu_S - \mu_N}{\sqrt{\frac{1}{2}(\sigma_S^2 + \sigma_N^2)}}$$

where  $\mu_S$  and  $\mu_N$  are the mean responses of the signal + noise and noise distributions, respectively, and  $\sigma_S$  and  $\sigma_N$  are the standard deviations.

**Visual Detection Task, Fig. 2** Calculating the sensitivity index as a measure of visual detection performance

Additionally, functional magnetic resonance imaging (fMRI) has shown that activity in the primary visual cortex (V1) correlates with accuracy on a visual detection task (Ress et al. 2000). Heterogeneity of neuronal responses in this area also correlates with greater ability to detect stimuli (Montijn et al. 2015). Other regions show activation patterns specific to “oddball” stimuli, motion detection, or detection of emotional content, which can be detected using fMRI or event-related potentials (ERPs).

## Applications

Visual detection tasks have been used in many psychology and neuroscience experiments, both in humans and animals. Specific types of tasks commonly used include visual flash suppression tasks, rapid serial visual presentation (attentional blink) tasks, and go-no go tasks. By assessing participant accuracy and reaction times under different conditions, researchers can learn about how factors such as attention, emotional content, and the presence of distractor stimuli affect detection. Visual detection tasks have implications for clinical practice, through improving detection accuracy in medical imaging. They can

also aid in improving detection for security purposes and for operating automobiles and aircrafts.

## Factors Affecting Visual Detection

There are a myriad of factors that affect whether or not a signal is detected. These include the properties of the stimulus (e.g., contrast, length), properties of proximal stimuli (e.g., presence of flankers, masking), and attributes of the observer (e.g., attention, training). Contrast, the difference in luminance between the background and the stimulus itself, is the feature most commonly manipulated in detection experiments, with a greater contrast making the stimulus easier to detect. However, other features such as the length and eccentricity of the presentation also make a difference. The longer a stimulus is shown, the more likely it is to be detected. If a stimulus is presented between the subliminal and supraliminal thresholds, as is common in priming experiments, it may be unconsciously perceived but the observer will not be able to report what they saw. Detection thresholds also increase with eccentricity of the stimulus (Palmer et al. 2007).

Proximal stimuli such as masking and flankers also affect difficulty of detection. Masking is when another word or set of symbols is presented immediately after the target stimulus to eliminate any after-image, making the target stimulus more difficult to detect. Flankers are stimuli presented next to the target and make it more difficult to perceive a faint stimulus. However, when stimuli of other modalities are presented at the same time as a faint visual stimulus, such as a sound played during a light detection task, these stimuli may undergo sensory integration to make the visual stimulus appear more intense (e.g., Stein et al. 1996). Even imagined stimuli may either facilitate or interfere with target detection depending on factors such as image location (Arterberry and Craver-Lemley 2002).

Other important features include observer characteristics. For instance, stimuli will be perceived more quickly and accurately if attention is placed on or drawn to that location. This is due to elevated activity in the primary visual cortex in response to attention that is thought to improve signal detection (Ress et al. 2000). Detection ability can also improve due to training, and response bias, as a result of participant goals, may produce changes to the threshold (e.g., if it is crucial not to miss a stimulus, an observer may respond “present” more frequently, shifting their responses towards more hits and false alarms and fewer misses and correct rejections).

Finally, the emotional significance of a stimulus is important in determining whether it gets perceived. For example, faces made imperceptible through visual flash suppression are more likely to reach blindsight and to be consciously perceived if the expressions are emotional (Oliver et al. 2015). Additionally, emotional stimuli that are shown in close proximity before neutral target stimuli in an attentional blink task make it more difficult to perceive the neutral stimuli (e.g., Most et al. 2005).

## Conclusion

Visual detection has been studied for decades, using both human and animal experiments as

well as computerized models. Experiments make use of visual detection tasks to examine phenomena such as attention, perception, and emotion processing. They also play an important role in many fields such as clinical diagnosis, security, and aircraft safety. Many factors go into determining the ability of humans and animals to detect stimuli, each informing us about how the brain functions to perceive objects in the world around us.

## Definition and Psychological Perspectives on Visual Perception

Visual perception is a brain process that actively detects and interprets neurological signals that were transduced from light. Much of what is known about visual perception has been well studied and understood with respect to human vision. The understanding of visual perception varies among researchers within behaviorism, Gestalt psychology, and cognitive psychology (Gregory 1997).

Behaviorists focus less on the inner workings of the mind and demonstrate that learned behavior is explained by chains of conditional responses. This behavioral explanation for visual processing falters, as perception is said to be a function of stimuli directly, rather than as a result of the internal processing of the mind related to those stimuli (Gregory 1997).

In Gestalt psychology, visual perception is interpreted as being greater than the sum of stimuli that make it up and organizing heuristics are based on certain laws, such as closure, common fate, and contiguity of close-together features (Gregory 1997). The law of closure describes a pattern when an image is incomplete but is arranged in such a way where an observer is able to describe a complete image, even with missing information (i.e., the Kanizsa's Triangle, Fig. 1) (Gregory 1997). Common fate occurs when objects are moving in the same direction, and as a result, they appear as moving “together.” Contiguity of close-together features describes how the brain organizes shapes when objects are positioned close together, so they appear as a group to an observer.

Cognitive processes related to problem solving and visual perception have historically been thought of as separate from one another. Early physiological psychologist Hermann von Helmholtz viewed perception as unconscious inferences, therefore pivotally linking thought to visual processing. Cognitivists focus less on the relationship between stimulus controls of perception and behavior but emphasize general knowledge, learning, memory, attention, and logical thinking as focal points in the study of visual

perception with varying degrees of success (Gregory 1997).

## Visual Biology, Perception, and Cognition

Visual perception is informed both by neurobiology and cognitive science (Clemente et al. 2010; Domjan and Grau 2015; Shimojo et al. 2001). The visual process occurs when light hits the retina, stimulating a change in opsin protein configuration in photoreceptors and flooding a transducing cell with sodium ions. Photoreceptors are not spread evenly on the retina, as the greatest concentration of rods can be found in the peripheral areas, while high-resolution cones are concentrated in the central fovea (Breedlove and Watson 2017). Light stimulation in photoreceptors causes a graded potential in bipolar cells that are, interestingly, positioned in front of the retina where light goes to stimulate transduction. This arrangement has interesting implications for visual perception in the brain as a great deal of “post-processing” is necessary for a clear image to form in the mind. Further positioned in front of the retina are the ganglion cells which together form the optic nerve where information is sent to the brain (Shimojo et al. 2001). The process from sensation to perception in the brain is a

multichanneled path (Fig. 2) organized by early, form, and movement processing.

*Early processing: Frequencies and contours.* The visual cortex of the brain is divided into areas that have specialized contributions to the visual system (Breedlove and Watson 2017). The primary visual cortex in mammals (area V1) contributes to the recognition of spatial frequencies (Fig. 3), orientation, and color (Hubel and Wiesel 1962). V2 processes additively to what V1 does and adds information by aiding in the perception of contours (von der Heydt et al. 1984). Mainly fed by neurons from the Lateral Geniculate Nucleus (LGN), area V1 has within it a series of neurons organized into ocular dominance columns (ODCs) that benefit spatial frequency recognition (Shmuel et al. 2010) and are thought to be important in binocular vision (c.f. Horton and Adams 2005). The ODCs consists of cell bands that respond to various stimuli presented to an individual (Breedlove and Watson 2017). This was first identified by Hubel and Wiesel in cats through their responses to the orientation of light stimuli at the neuronal level. Slits of light as well as rows of dots with the same orientation were used to stimulate cells in the retina. From there, the signal was traced to cell units in the V1 area of the visual cortex. The experimenters isolated each eye to record the relative contribution of the monocular signals, before looking at the contributions of both eyes in aggregate. This experiment paved the way for understanding how visual physiology ultimately shapes perception and therefore represents a foundational work of neurobiology (Wurtz 2009). From a proximate viewpoint, Hubel and Wiesel also laid out the columnar organization of neurons in V1, showing convergence with the somatosensory cortex in mammals (Mountcastle 1957).

*“What” processing: Shapes and forms.* Area V4's role is more firmly related to form and attentional processing and has neurons tuned to simple shapes as it takes input from V1 and V2 (Moran and Desimone 1985). Areas V2, V4, and the IT are involved in form identification, but each area has a specific role. For example, area V2 specializes in the interpretation of images with contours that project an illusion. Although, it is thought that

**Visual Perception, Fig. 2** Visual processing pathway. *LGN* lateral geniculate nucleus, *V1* primary visual cortex, *V2* *V3*, and *V4* visual areas 2, 3, 4, 5 and *IT* inferior temporal cortex. Area *V1* is associated with spatial frequency recognition, orientation, and color perception. Area *V2* is involved with form identification, specifically

illusory contours of images. Area *V4* has a role in form identification. *IT* functions in recognizing complex images, such as facial recognition. Area *V3* is involved in global movement perception, while area *V5* (MT = middle temporal) functions in motion detection and control of eye movements

**Visual Perception,**

*V1* might feedback into this process (Ramsden et al. 2001), it is really *V2* leading to higher cortical areas that is responsible for our perception of things like the brightness of negative space in the Kanizsa's Triangle illusion (Fig. 1). *V2* is tuned to aspects of spatial frequency and color and is thought to relate to object recognition memory (López-Aranda et al. 2009).

Both *V1* and *V2* mostly rest on the geniculate system; however area *V4* is part of the extra-geniculate or pulvinar system (although it has strong connections to *V1* and *V2*) (Roe et al. 2012). This is a parallel pathway outside direct mediation by the LGN (Tabei et al. 2015). Just like *V2*, this structure has cells that respond to spatial frequency and orientation, but there are

also cells with a stronger preference to respond toward different wavelengths of light. Much focus of late has been on the role of V4 in top-down visual attention processing and bottom-up object recognition (Roe et al. 2012). The IT contributes to recognizing complex forms (Breedlove and Watson 2017) and is the final area for visual object processing. The IT also contains specialized processors for recognizing specific kinds of objects, such as faces (Tsao et al. 2006). Individual experiences may shape how the IT area processes these stimuli, indicating connections with other cortical areas (Breedlove and Watson 2017).

*Where things are: Location processing.* Areas V3 and V5 aid with perception of motion (Born and Bradley 2005). V3 is thought to function in our processing of global movement and V5 functions in motion detection and control of eye movements (Dursteler et al. 1987). While the exact organization of V3 is up for some debate, V5 is also part of the extrageniculate system, but this center is not functionally additive the way V1, V2, and V4 are and has separate pathways for foveal vs. peripheral signals (Palmer and Rosa 2006).

## Color Perception

### Neurology of Color Perception

The assignment of color occurs in three stages (Breedlove and Watson 2017; Shimojo et al. 2001). The first stage (transduction) occurs on the cone photoreceptor itself. The second stage of processing occurs within the secondary neuronal tissue of the retina where inhibition and excitation of surrounding circuits play a role in shaping the signal that is inevitably sent to the brain (Kuffler 1953). From there the signal is sent through the LGN to area V1 where information is sent to other areas of the visual cortex to which color perception is finalized in the third stage (Breedlove and Watson 2017).

### Theories of Color Perception

Within the science of color vision, there are opposing hypotheses of which neither is fully capable of explaining color vision: trichromatic theory (Young 1802) and opponent-process

theory. The trichromatic hypothesis supports the idea that there are three different cone receptors, blue, green, and red, each with their own path to the brain (Young 1802). This is exhibited in certain primate species, while other mammalian species have dichromatic vision (Breedlove and Watson 2017). In contrast, the opponent-process theory (which applies to more processes than just color vision) supports the idea that there is a production of opposite reactions in response to different wavelengths of light (Breedlove and Watson 2017). Ewald Hering postulated about three independent receptor types which all have opposing pairs: white and black, blue and orange, and red and green. This would later be refined to two pairs, blue and yellow and red and green, where excitatory and inhibitory patterns of firing would affect the ultimate perception of color with the two components of each mechanism ultimately opposing each other. Therefore, one can have colors that appear greenish-blue or blueish-red, but not reddish-green or yellowish-blue. Neither hypothesis can explain color vision by itself; however the trichromatic theory explains how the three types of cones detect different wavelengths, while opponent-process theory explains how the cones connect to the ganglion cells, where the opposing elements inhibit each other to determine how color is perceived (Hurvich 1985).

### Individual Differences

Color perception varies between organisms since there are differences in wavelength sensitivity as well as the availability and distribution of an organism's rods and cones (Shettleworth 2010). In humans, different photoreceptors are sensitive to different wavelengths of light, with cones having peak sensitivity to 420 nm, 530 nm, and 562 nm and rods having peak sensitivity to 500 nm (Fox 2016). Humans can observe shadows as both dark and blue, whereas non-human animals with UV vision can see shadows as dark with shades in the UV spectrum (Troscianko et al. 2009). Many features of the eye, such as the sclera or corneal epithelium, are developed to suit an organism's habitat and the types of color stimuli they experience on a daily basis (Berta et al. 2015). For example, the increase

in water depth results in loss of color sensitivity which is shown in the retina of the red-tailed black shark whose eye consists mainly of rods and green and red-sensitive cones (Levine and MacNichol 1982). For most mammalian species with color vision, G. H. Jacobs proposed a range of color vision into four categories (Breedlove and Watson 2017). Diurnal primates, like humans, exhibit exceptional trichromatic vision. Dogs and pigs have two types of cone photopigments and large number of cones which results in a strong dichromatic vision. A weak dichromatic vision is present in species such as cats and coatis, and they also have two types of cone photopigments but a small number of cones. The last category is minimal color vision, where an organism has one type of cone pigment and relies on rod-cone interactions for wavelength discrimination; this is present in owl, monkeys, and raccoons (Breedlove and Watson 2017).

### Development of Visual Perception

The development of the visual system is affected by the environment and experience. For example, the eyes of aquatic organisms are adapted to the lower light levels found in their niche (Berta et al. 2015). Ganges River dolphins (*Platanista gangetica*) have relatively poor eyesight as selection pressures associated with living in an opaque fluid have reduced the function of this cetacean's eyes (Sinha and Kannan 2014).

It is essential for many organisms to have experiences with visual stimulation as a foundation for understanding what stimuli are available for the eyes and brain to process (Domjan and Grau 2015; Honigmann 1944; Troscianko et al. 2009). This is broadly outlined by the work of Gilbert Gottlieb (1976) who emphasized the role of experience in development. For example, human infants require a long period of locomotor experience for depth perception to be processed correctly, whereas other species, such as goats, do not require experience with movement to perceive depth (Adolph 2000). Stereoscopic vision in primates is fully dependent on experience shaping the timing and pattern of gene expression, as

infant rhesus monkeys that have had their binocular vision impeded by prismatic lenses do not develop the excitatory binocular neurons necessary for normal binocular depth perception (Crawford et al. 1996).

### Comparative Evolutionary Analysis in Visual Perception

The comparative study of visual perception, and especially its development, remains a poorly studied field and could shed light on the evolution of our own visual system (Shettleworth 2010). On the evolution of visual perception, the placement of an individual's eyes can indicate the extent of binocular vision that is required by ecological factors such as the need to hunt (Shettleworth 2010). Such vision results in greater visual acuity in parts where there is overlap of the visual field (Clemente et al. 2010; Shettleworth 2010). For example, the Australian wolf spider's (*Lycosa leuckarti*) eyes are positioned both anteriorly and posteriorly. Its overlapping binocular anterior and posterior medial eyes are used for distance judgment and prey capture and its non-overlapping posterior lateral eyes are used for long-range predator and prey detection (Clemente et al. 2010). In aquatic species like bottlenose dolphins (*Tursiops truncatus*) and goldfish (*Carassius auratus*), the eyes are positioned laterally, which allows them to potentially perceive a great deal around them but also allows them to view objects independently of the head on viewing angle since they can move three dimensionally and view the objects from different orientations (Cozzi et al. 2017). Consequently, bottlenose dolphins are able to move their eyes independently where one eye may look forward and dorsally, and the other eye may look rearward and ventrally (Cozzi et al. 2017). Evidence suggests that trilobites had some of the earliest eyes seen in the fossil record and because they contained a calcified cuticle, this structure was well-preserved. Not only was this an early eye, but it was likely a successful one as well, because this aquatic species maintained this visual system for about 270 million years (Clarkson et al. 2006). The likely visual field of

the trilobite's eye did not extend to objects above them since no predators or prey existed in that space at that time (Clarkson et al. 2006), giving a slightly angular look relative to the round eyes common in species today. Chitons have one of the more newly evolved eyes, characterized by aragonite-based lenses that allow their vision to operate in both air and water (Speiser et al. 2014). The convergent evolution of the trilobite and chiton mineral eyes show how they have both adapted to their similar environments in similar ways (Speiser et al. 2014).

## Visual Recognition in Birds

Gisela Kaplan

School of Science and Technology, University of New England, Armidale, NSW, Australia

## Introduction

The ability to visually recognize another individual may be a question of life and death. Recognition may be essential, be this for distinguishing friend from foe and for making split-second decisions of whether to approach or flee, or for courtship and mating as well as in parent-offspring interactions.

Not all recognition may be based on vision. A species may have a perceptual apparatus in which one sense dominates and others are negligible or even absent. In many organisms, communication and individual recognition may be multimodal, i.e., combining visual, auditory, or olfactory, vibratory, or gustatory cues to recognize each other.

In birds, as in humans and most diurnal primates, vision is one of the dominant senses. In these cases, vision is usually complex and is based on a highly developed system. Organization of eyes and position of eyes determine what is seen and how the brain can respond to visual inputs and, finally, how such information is processed and ordered into meaningful perception and memory.

### External Organization of Visual Fields

First, it is important to know where the eyes are positioned in the head, and that position can vary quite substantially from species to species. Frontally placed eyes, as in humans, mean that the axes of the eyes' optical systems are approximately parallel, and both eyes together can simultaneously gain very similar views of the same objects (Martin 2007). Owls and many of the nightjars, potoos, and frogmouths have frontally placed eyes and are among the few avian species with full binocular vision.

Second, it is also important to take note of the actual visual field of a given avian species. Generally, the axes of the eyes' optical systems may have a number of important variations that may help specific species to see what they need to see most, usually food and predators (Fig. 1).

Although, as shown in Fig. 1, eye position can vary a great deal among all extant birds, in songbirds it tends to be far more uniform, with eyes placed on either side of the head, in the midline of the mandible. Such laterally placed eyes mean that visual information from each eye represents and entirely different image that is monocular. Binocular vision is relatively limited but sufficient at close distance to gain a binocular view of food, or when feeding offspring directly to the beak (Fig. 2).

Figure 2 shows quite clearly that visual processing is affected by the visual field. Most birds have a small binocular field of just 15–35° but a wide monocular field enabling birds to focus on two essential things for survival: food sources and predatory threats. If predatory threats are significant and food searches demand lowering the head, the eyes may be situated further up in the skull as in the woodcock, in ducks, and in most shorebirds so that overhead threats can still be monitored while feeding (Fig. 1a, b).

### Visual Recognition via Imprinting

An exciting discovery of the twentieth century was to have identified the process of imprinting, described as a type of learning by “which an animal restricts its social preferences to an object after exposure to that object” (McCabe 2013). Filial imprinting occurs shortly after birth or hatching, and the intermediate and medial mesopallium (IMM) in the brain is a memory store for visual imprinting. After imprinting on a visual stimulus, neuronal responsiveness in IMM is specifically biased toward the imprinting stimulus (Bateson and Horn 1994). We know that chickens, ducks, and indeed all precocial birds, which are self-feeding and feathered at hatching, will follow a parent based on this imprinting, and if another attractive stimulus is presented instead, they will follow that too (Bateson and Horn 1994). Imprinting applies only to precocial species but not to the thousands of songbirds that are altricial (i.e., are entirely dependent on parents and stay in the nest until they are fully feathered and developed). Nevertheless, in all species, reliable memory formation is essential.

### Processing of Information in the Brain

Information from the eyes is processed separately and, importantly, not by the same side of the brain in which the eye is located, i.e., the optic nerve is “cross-wired” so that the opposite hemisphere receives the input. Each brain hemisphere (and thus each eye) is specialized to process information differently, and it controls different functions and behavior. The left hemisphere (right eye)

**Visual Recognition in Birds, Fig. 1** *Topography of the binocular visual fields in birds.* The binocular visual field is where inputs go to both eyes, and its size depends on the position of the eyes in the head in relation to the beak and the top of the head. (a) Egrets (great egret: *Ardea alba modesta*), as in many shorebirds, have eyes as close as possible to the upper mandible and can use binocular vision just beyond the end of the beak. (b) Woodcock (genus *Scolopax*) eyes are placed high up to be able to scan the skies while probing for food. (c) Birds of prey (brown goshawk, *Accipiter fasciatus*, left; golden eagle, *Aquila chrysaetos*, right), as top predators, need good

binocular vision around the tip of the beak, and they bring their claws clasp the prey into this field of vision. (d) Blue and gold macaw, *Ara ararauna*, as all macaws and other large birds, have a very wide binocular field of vision; despite their size, they still need to fear large raptors. (e) Owls, potoos, and frogmouths have frontally placed eyes. (f) The extremely large African shoebill, *Balaeniceps rex*, is the bird with probably the smallest binocular visual field because the beak obstructs it, and note that the eyes are set deep under eye ridges, and therefore the visual field is largely confined to front and a little to the side (Adapted and expanded from Kaplan and Rogers (1999))

broadly categorizes stimuli, distinguishes food from nonfood, and identifies routine visual stimuli (invariance) while the right hemisphere (left eye) recognizes members of the group and individual faces (Rogers 2011).

In the few species tested so far, viewing with the left eye (right hemisphere) has been confirmed for predator recognition in wild Australian magpies, *Gymnorhina tibicen* (Kaplan 2016) and for individual face recognition in domestic chickens and pigeons (*Columba livia domestica*). As in magpies, chicken and pigeons turn their heads to view the stimulus with the left eye (right hemisphere processing). Chicks also use the left eye (right hemisphere) to view a model social partner and whenever viewing familiar social partner at a

distance, but when they look at an attractive stimulus on which they might imprint but had not yet imprinted (e.g., a hen), they use the right eye (Vallortigara and Andrew 1994).

To test this further, Ocklenburg and Güntürkün (2018) devised experiments in which domestic pigeons were shown two-dimensional images of a person and the pigeon's task was to peck on an image when there was a person contained in it. First, the person was shown in a normal upright position, and in following images it was upside down or splintered in various ways so that part of the body was detached, missing, or in the wrong position. When pigeons viewed the images monocularly with the right eye (left hemisphere), they pecked only the keys that most resembled the

**Visual Recognition in Birds, Fig. 2** The visual field of the Australian magpie clearly showing the substantially greater size of the monocular fields (Adapted from Rogers and Kaplan (2006))

normal shape and position of a person, but when the right eye was occluded and the images were viewed only with the left eye (right hemisphere), the pigeons pecked almost all images, whether upside down, body parts detached, or body parts missing. These experiments demonstrated very clearly that the left hemisphere/right eye can only distinguish between broad categories while the right hemisphere/left eye can detect fine details, i.e., collect substantially more detailed information about a person or conspecific than by right eye viewing (Ocklenburg and Güntürkün 2018).

### Facial Recognition: the Cognitive Dimension

A novel stimulus seems to require more than monocular viewing. Songbirds examine a novel item by viewing it first with one eye and then with the other eye, turning their head to get a monocular view from each eye separately, as was shown in a study on zebra finches, *Taeniopygia guttata* (Rogers et al. 2018). This may well be so to enable the brain to lay down a full memory of all stimulus features, thus first using both hemispheres to do

so. Avian species so far tested can recognize, i.e., remember, individuals of different avian species and mammals (such as a pet dog or pet cat) including individual human faces by visual recognition alone (Cornell et al. 2012). This ability, again, is a function of the right hemisphere.

It becomes an important cognitive achievement when visual recognition of an individual's face is linked to his/her behavioral characteristics. For instance, when humans are considered dangerous or friendly by American crows, *Corvus brachyrhynchos*, that information is combined and the new knowledge then spread socially among their group (Cornell et al. 2012). Forming an image of an individual human face is an extraordinary feat and has now been recognized as requiring more than mere image memory. It involves assessment, connecting a visual input with characteristics of the person to which this face belongs. Depending on the results of such assessment, this may alter the behavior of the birds entirely; for instance, it may include warnings about specific individual people or other species or, alternatively, may result in affiliative behavior expressed in preening, play behavior, gift giving, and/or even seeking the company of that person or conspecific. Australian magpies, as well as the unrelated Eurasian magpies, *Pica pica*, have excellent facial recognition of humans (Lee et al. 2011) that they use for risk assessment of the safety of their own nest. Come breeding time, the male will selectively mob only those individuals that are unknown or have made gestures that could be interpreted as hostile or dangerous. Remarkably, such detailed information about individuals is retained from one breeding season to the next. So far, we only have anecdotal evidence, but it appears that the memory of the behavior of specific humans may remain intact for many years (Kaplan 2016).

As in humans, visual recognition in some birds may thus involve an understanding of another individual as a separate entity with separate actions and intentions. The ability to understand this "otherness" is considered part of "theory of mind." Distributing information from one to another, from the knower to a recipient absorbing the knowledge and acting in

accordance with that information, is perhaps the most remarkable ability.

## Visual Recognition of Prey and Predators

Callen M. Inman

Department of Integrative Biology, University of Texas-Austin, Austin, TX, USA

## Synonyms

[Visual predator identification](#); [Visual prey identification](#)

## Definition

The process by which predators identify prey and prey identify predators based on visual input.

## Introduction

Predation, in which one organism consumes all or part of another organism for nutrition, has evolved many times throughout the history of life. Predation is a potent selective force that restructures food webs, redistributes nutritional resources, and can send predators and prey into coevolutionary arms races.

The life-dinner principle provides a useful lens for understanding the evolutionary dynamics underlying the visual recognition of predators and prey. According to the life-dinner principle, prey almost always bear larger fitness costs than predators (Dawkins and Krebs 1979). On the one hand, the failure of prey to escape predators typically results in a loss of life. On the other hand, the failure of a predator to capture prey simply results in the loss of its dinner. Thus, selection pressure on prey to avoid predators is almost always higher than the selection pressure on predators to successfully obtain a given prey organism.

Despite its suitability for understanding the behavioral evolution of predators and prey, the life-dinner principle has not been without its critics and proposed alternatives. Abrams (1986) noted that if a predator fails a sufficient number of

times to catch prey, it suffers fitness costs as large as those that a prey organism incurs if it fails to escape a predator: namely, death. Additionally, Humphreys and Ruxton (2020) suggest that factors besides the life-dinner principle may explain asymmetries in the degree of adaptation between predators and prey. For example, improved anti-predator defenses in prey may result in a higher prey density, thus increasing the rate at which a predator encounters prey and relaxing selection pressure on adaptations for prey capture.

The life-dinner principle predicts that prey will evolve elaborate adaptations in response to predation. Morphological and adaptations may include a cryptic appearance, use of habitats concealed from the view of predators, and a suite of toxins that the organism emits. And, though the selection pressure for them to evolve may be weaker, the adaptations of predators to successfully obtain prey may include speed, agility, and aggressive mimicry of harmless organisms. In addition to these morphological and behavioral adaptations, some adaptations of predators and prey may be cognitive. Cognition (the neuronal processes associated with the acquisition, retention, and use of information about the environment) can range from lower-level memory to the higher-level thinking that characterizes humans (Dukas 2002). Prey should be expected to employ some level of cognition to assess the threat a predator poses, and predators should be expected to employ information processing to differentiate prey from nonprey and make captures that they can successfully use to their benefit (Barrett 2015).

## Vision

Many organisms obtain information about the environment through the visual system. Eye-like structures have emerged independently an estimated 40 times throughout the history of life on earth, ranging from light-sensitive cells in earthworms to compound eyes in fruit flies. Despite their varied evolutionary histories, the proteins that catch photons and bend light rays are remarkably similar across taxa (Land and Fernald 1992).

Using this uniform process for converting light energy into nerve impulses, predators and prey must successfully recognize each other despite variation in illumination conditions, viewing angles, and obstruction by other objects. The organism must successfully generate a retinal image of the object, and then must categorize that image in a class of objects that the organism has previously encountered.

## Recognition

To understand how recognition systems evolve, it is important to focus on the behavioral responses that successful recognition causes. Recognition systems are adaptive or maladaptive only according to the behavioral, developmental, or physiological responses they generate in organisms (Dukas 2004; Liebert and Starks 2004). Selection acts on an organism's ability to recognize cues in its environment based on the fitness advantages that this ability confers. These advantages include finding mates, finding food, or avoiding danger. The recognition ability of one organism can also affect the fitness of the organism being recognized. These consequences range from beneficial in kin discrimination to deadly in prey recognition. Failing to respond to cues that a predator is nearby carries a much greater penalty than failing to notice cues of mate quality or food availability (Lima and Dill 1990).

## The Visual System and Predator Detection

The visual system has several different components that can act both as constraints to fitness in the face of predation as well as adaptations that enhance predator detection ability. The configuration of the visual field, or the degree of visual coverage around a prey organism's head, varies across different types of organisms. The visual field can act as a constraint because the shape of the visual field confers a trade-off between sensitivity and accuracy. Visual acuity, temporal visual resolution (how quickly the retina perceives

temporal changes in visual stimuli), visual contrast (ability to resolve a stimulus against a background), the width of the visual field, and motion detection all play important roles in predator detection ability (Tyrrell and Fernandez-Juricic 2015).

## Visual Acuity

Visual acuity refers to the sharpness of vision at a given distance from the observer. The visual acuity of an organism determines how far away a predator could be from the organism and still be detected. Studies of allometry have shown that visual acuity is hyperallometric to eye size. Allometry is the study of the relationship of body size to anatomy and physiology. A perfectly allometric relationship occurs when two body parts increase in size in proportion to each other as body size increases. Visual acuity is considered hyperallometric to eye size because, when the logarithm of visual acuity and the logarithm of eye size are plotted against each other, the log of visual acuity increases by a factor greater than one. Because eye size only scales *allometrically* with body size, larger organisms tend to have disproportionately better visual acuity than smaller organisms. Birds have higher visual acuity than other similarly sized animals due to their eyes that are often large for their body size, which may confer an advantage in detecting predators from a distance (Martin 2007).

## The Visual Field

Vertebrate species vary in their degree of binocular overlap, often according to an organism's vulnerability to predation. The eyes in humans and other closely related primates face in the same direction, which is a feature known as frontal convergence (Heesy 2004). However, many prey organisms, such as rodents and hoofed mammals, have lateral-facing eyes that have a small area of overlap. Organisms with such lateral-facing eyes may have a wider visual field, which assists with predator detection across a wider area. Lateral-

facing eyes may move independently of each other, further increasing the probability that a predator in the vicinity will be noticed.

## Visual Resolution

In addition to visual acuity and visual field configuration, predator detection may also depend on overall visual resolution, which refers to the average resolution across the whole visual field as determined by eye size and the average density of photoreceptors across the whole retina. If there is a steep change in cell density across the retina, individuals rely mostly on their retinal center of vision (rather than periphery), increasing the number of eye/head movements required to gather information, i.e., scanning behavior (Fernandez-Juricic et al. 2010). On the other hand, a small change in cell density would allow individuals to also rely on the retinal periphery, providing a larger portion of the retina with high-quality information and reducing the need for a high frequency of head/eye movements. A species with a steeper cell density profile may have lower chances of predator detection because it collects fewer retinal snapshots per unit of time, and there is a smaller retinal area with high resolution within each snapshot.

## The Cognitive Ecology of Predator Recognition

The ability to recognize predators allows prey organisms to successfully avoid dangerous encounters and to continuously monitor the level of risk around them (Lima and Dill 1990). How prey organisms respond to the risk of predation now is shaped by predation pressure over evolutionary time, as well as by the rate at which an individual organism encounters predators in the environment. The predation risk allocation hypothesis predicts that an organism should allocate the most energy into predator monitoring and avoidance when in infrequent, high-risk situations and allocate the least amount of energy to predator monitoring when in frequent, low-risk situations

(Lima and Bednekoff 1999). Intergenerationally, selection pressure on prey is expected to be strongest for costly predation events that occur every generation with great frequency. This hypothesis has implications for predator recognition in prey. Prey organisms should easily learn to recognize or have an innate response to predators that are encountered every generation and that pose a high risk to prey. On the other hand, prey organisms may not learn to recognize predators which pose a lower risk as easily. Prey that are capable of learning predator identities while adjusting the intensity of their response to match their level of risk should be at a substantial selective advantage (Manassa et al. 2014).

Learning plays an important role in predator recognition. Organisms can learn to recognize species through social learning or individual learning. In species with social learning of predator recognition, less experienced individuals commonly learn about predators from more experienced individuals. This social learning eliminates the need for an individual to directly face the risk associated with confronting a predator itself (Dowell 1986). In species that never encounter adults of their own species as young, an individually learned response is more likely to evolve. Supporting these predictions, recognition of predators appears to have evolved in some bird species, such as Australian brush-turkeys that lack parental care. In the absence of parental guidance, young must be able to recognize and avoid predators on their own (Göth 2001). In contrast, in bird species with parental care, such as grey partridges and pheasants, naive chicks also learn to respond to certain stimuli on their own, but they later learn a more sophisticated behavioral response from their parents (Dowell 1986).

Innate recognition of predators may evolve in species in which the costs of learning are particularly high (Berejikian et al. 2003). Learning requires sampling of the environment, which can be costly in terms of time, energy, and the potential for mistakes (Snell-Rood 2013). In addition, the neural tissue associated with learning is expensive and may involve trade-offs with reproduction and fecundity. The amount of energy devoted to learning tasks may thus reduce the

amount of energy available to invest into reproduction, thus favoring the evolution of predator avoidance strategies that are less learning-intensive (Lefebvre and Sol 2008). In particular, innate recognition of predators may evolve when learning costs are high, and when the benefits of having a more plastic predator recognition response are negligible (Berejikian et al. 2003).

How prey sensory and cognitive systems both constrain and are driven by selection on prey by predators is a key question in the emerging field of comparative psychology (Emery and Clayton 2009). Examining differences between species in the mechanisms and abilities underlying predator recognition is crucial for understanding the degree to which predator recognition is affected by different selective environments (Polo-Cavia et al. 2010). As well, there is well-documented potential for responses to predators to be changeable: affected by such nongenetic variables as a stressful social environment, toxic pollutants, and the rate at which an individual encounters certain predators within its lifetime (Snell-Rood 2013).

## Prey Recognition

In ecological theory, the “landscape of fear” represents levels of predation risk as peaks and troughs, which are reflected in similar peaks and troughs in antipredator behavior in prey organisms, or “fear” (Laundré et al. 2010). In contrast, the behavior of predators is driven by the richness and size of a prey community in various “patches.” Importantly, predators are not a static environmental risk faced by prey, but they are expected to respond strategically to prey behavior over time. Producers are organisms that convert an abiotic source of energy into organic compounds. Consumers are organisms that are unable to make their own energy and instead rely on the consumption of other organisms. Animal prey (consumers) are only taken by secondary, tertiary, and quaternary consumers, whereas primary consumers only eat producers. Prey organisms that are consumers are usually more mobile than producers. Thus, high-value resource “patches” composed of consumers tend to be less spatially and

temporally predictable than resource patches composed of producers. Because of this greater dispersion and lower predictability of food resources, prey search by higher trophic level predators can be a demanding task.

How do such predators accomplish the task of prey search? While predators rely on a variety of senses to detect and capture prey, including olfaction and audition, many avian and mammalian predators are especially reliant on vision. Visual detection of prey is influenced by a number of factors. The spectral properties of ambient light in a given environment influence how conspicuous objects are against the background. Prey organisms will more readily be detected in high light than in shady environments and in environments with few obstructions rather than environments densely packed with vegetation or debris (Uy and Endler 2004). Visual recognition to prey is also affected by properties of the predator's sensory system, including how the predator perceives different wavelengths of light. In addition, predatory foraging strategies vary widely, from stealth to sit-and-wait and to cooperative hunting, affecting how quickly and easily a predator will recognize prey. In addition to being influenced by a predator's ecology, prey recognition is also impacted by the characteristics of prey themselves.

## Prey Characteristics and Recognition by Predators

Different characteristics of prey affect the evolution of predator visual systems, including the visual perceptual systems of the prey, prey crypticity, and prey toxicity.

Animal visual perceptual systems are necessarily constrained. Animal brains have a limited rate of information processing. Even if they have a 180- to 360-degree view of the surrounding environment at any one time, individuals must restrict the amount of information they process at any given time (Dukas 2002). A consequence of limited information processing is that animals selectively attend to salient environmental stimuli. Animals rely on cognitive "search images" that

allow them to efficiently attend to habitats, food, and mates.

Like prey, predators face a trade-off between having a wide attentional angle and perceiving the finer details of prey. A wide attentional angle allows for a predator to search a large area, helping it to successfully find any conspicuous, easily noticeable prey within its field of vision. But finding a more hidden, cryptic target may require a narrower attentional angle and a lower search rate (Gendron and Staddon 1983). When searching for prey, predators generally target the most conspicuous prey phenotypes. Generally, factors determining a prey's conspicuousness may include such variables as high achromatic contrast in the prey's habitat or color patterning that reflects light at the peak of a predator's spectral sensitivity.

Cryptic phenotypes are less discernible than conspicuous phenotypes, but they can still be learned and recognized by predators. When avian predators are trained to recognize cryptic prey, they form a search image of the most abundant type in the environment (Dukas and Kamil 2001). Predators tend to form a search image of the most abundant type of prey due to information processing constraints. It is considerably easier to keep a search image of one prey phenotype in working memory and to selectively attend to patterns matching it than to look for patterns matching two or more search images simultaneously (Dukas 2002). As the type's numbers decrease (due to higher predation rates than on less frequent types), predators engage in perceptual switching, changing their search image to target the prey species that became relatively more abundant (Bond 2007). The information processing constraints imposed on predators by search images and perceptual switching are thought to be a main driver of the evolution of color polymorphism in many cryptic prey species. These constraints result in apostatic selection on prey phenotypes, in which a given prey phenotype's fitness is negatively correlated with its frequency in the population.

Dawkins and Krebs's salient life-dinner principle states that prey should be under stronger selection to avoid any given predator than

predators to catch any given prey. However, the asymmetry in selection on predators and prey may be reduced when prey are dangerous. For most prey that are noxious, predators learn that they are noxious by encountering them individually. The encounters are rarely dangerous, and prey that are easier to learn to avoid (with bright, memorable patterning or coloration) generally have an advantage. This is the basis for the evolution of aposematism as well as Batesian and Mullerian mimicry systems. However, some prey are actually dangerous to predators, resulting in serious illness or even death if consumed.

## Conclusion

Developing an integrative understanding of the visual recognition of predators and prey is an interdisciplinary endeavor. It involves a complex network of fields, such as cognitive psychology, evolutionary ecology, neuroscience, and behavioral ecology. However, the literature on visual recognition of predators and prey has been dominated primarily by studies on birds and falls largely within the domain of evolutionary ecology. Bird studies likely dominate this literature because nonavian organisms, such as most mammals and many fish, may be less reliant on visual recognition than birds. Future studies should explore the importance of visual recognition of predators and prey relative to other forms of recognition, such as auditory and olfactory recognition, in other taxa. In addition to the advent of comparative methods, the theory and empirical evidence behind ontogeny and developmental plasticity have grown in recent decades. Recognition is a cognitive process, and like all cognitive and behavioral processes, it is not entirely hard-wired, but also contingent on environmental inputs (Snell-Rood 2013). Examining how recognition manifests itself ontogenetically will help answer critical questions about how knowledge acquired from previous experiences can shape predators' and prey's ability to recognize and avoid each other. An integrative

perspective that takes into account the flexibility of many cognitive and behavioral traits will further our understanding of the proximate and ultimate factors behind predator and prey recognition. Additionally, examining how these factors differ across evolutionarily distant groups (such as arthropods and vertebrates), as well as between closely related species, will be crucial to advancing this fertile area of research.

## Introduction

In everyday life, animals spend much of their time with looking for something. They need food, nest-building material, or mates and compete with conspecifics for all these pivotal resources. Unfortunately, their location is mostly uncertain, and they are typically embedded within an environment full of irrelevant stimuli (**distractors**) competing for attention and hindering identification of the actual search item. Many animals actively try to impede their detection as prey or predator by camouflaging and hence, blending into the surrounding. Thus, an individual requires efficient strategies to search in the visual field, which facilitate quick detection of significant objects. The difficulty of **visual search** depends on factors like scene complexity, number of distractors, and similarity between search objects, distractors, and background. This is a computationally demanding task. Since neuronal resources are limited, visual systems cannot process all incoming information in parallel and therefore have to filter out relevant stimuli while suppressing responses to distractors or noise. Thereby, especially attentional mechanisms mediate selection of cues and guide gaze during search.

Although pivotal for all visual animals, major models of visual search strategies are coming from human psychology and are intimately related to theories of attention (Eimer 2014; Knudsen 2007; Wolfe 2003). Due to the interrelations between attention and visual search, search paradigms are typically used to

investigate attentional processes. Recent comparative studies, however, indicate an astonishing similarity of fundamental mechanisms between different vertebrate classes and even insects irrespective from profound differences in the organization of their neuronal systems (Nityananda 2016).

## Visual Search in the Laboratory

In a typical visual search experiment, subjects have to report the presence or absence of an object that is defined by a set of features (**target**) among irrelevant items (**distractors**), which differ in one or more dimensions from the target (Fig. 1). Objects are often presented on a computer screen but semi-natural setups can also be used (Fig. 2). While human subjects can be verbally instructed what to look for, animals firstly have to be trained onto the search target. This typically means that the animal learns to differentiate between a rewarded positive and a nonrewarded negative stimulus during a conditioning process. After reaching a learning criterion, the individual has to search for the positive item between varying numbers of distractor stimuli. Thereby, natural behavior of the tested species is used to analyze search performance. Pigeon, for instance, can be trained to peck onto stimuli presented on a computer screen within an operant chamber (Fig. 2a) while honey bees can learn to approach a rewarding “artificial flower” in a semi-natural experimental setting (Fig. 2b).

Experimental search is typically less complex than in natural surroundings. But difficulty of the task can be manipulated by changing the number of items, by the complexity of the target, or by the similarity between target and distractors or background. Search performance is measured as **error rate** (= erroneously indicating presence (**false alarm**) or absence (**miss**) of the target) or as **reaction time** (RT, time required to indicate presence or absence of the target). The relation between RT and number of presented items in the display (**set size**) is an important measure indicating the underlying search strategy. If RT rises

**Visual Search, Fig. 1** Complexity of visual search – (a) in an artificial display, a target (*yellow circle*) may pop-out since it is characterized by features that are very different from other items (*blue squares*) on the display; the target directly attracts attention and can be detected without detailed analysis during parallel search. (b) When target characteristics (*yellow circle*) overlap with that of the distractors, detection requires comparison and combination of different features (shape + color) during serial search. Although attention might be firstly attracted by one feature (e.g., yellow color), all objects must be scanned one by one until the target is identified. (c) Search in a (semi)-natural setting is typically even more complex since targets like edible grains (arrows) can be embedded within a complex background of distractors (similar looking pebbles). Detection requires detailed analysis of the scene during serial search

linearly with increasing set size, the subject presumably scans the items one by one until the target is found. This indicates a **serial search strategy**. If on the other hand, RT is independent from set size, the subject may observe all items at once. This pattern points to a **parallel search strategy**.

**Visual Search, Fig. 2** Typical experimental setups for visual search – (a) Animals like pigeons can learn to discriminate and detect stimuli presented on a computer screen. To this end, a pigeon may learn to peck onto a target (S+, O), which is reinforced with food while pecks onto a distractor (S–, X) leads to punishment (e.g., short time out; according to Blough 1979). (b) Insects like honey bees can

be trained to choose a colored disk (S+) among differently colored ones (S–). Discs include a feeder (*black dots*) that may provide sweet sucrose (S+) or bitter quinine (S–) solution. These “artificial flowers” are attached on the back of a box, which could be entered through an entrance hole (according to Spaethe et al. 2006)

## Steps and Mechanisms of Visual Search

Visual search proceeds along different steps, which confront the neuronal system with different problems. Because of the richness of the natural environment, it is impossible to process all visual input at one time. A major problem especially during natural-scene search is the decision how to scan the environment and hence how to disperse attention to select relevant information helping to find the search object. Thereby, **bottom-up processes** identify **salient**, conspicuous features, objects, or places, which directly attract attention. **Top-down processes** guide attention according to expectations about the appearance and localization of the search item and therefore consider **context** information that predict where the search object might be. Since mostly not all details of scenery can be analyzed in parallel, the visual system switches between **serial** and **parallel search mechanisms**, which differ in speed and accuracy and which are differentially efficient depending on the complexity of the search items, distractors, and scene.

Search starts by deciding what to look for. This implies that the individual has some expectations how the search object looks like. A search object is typically defined by a combination of features like shape, size, color, or texture. These features are used as templates guiding attention through

the visual scenery. **Attentional templates** are represented in working memory, which temporarily stores a limited amount of selected information for later processing. Incoming signals are permanently compared with these templates to select specific signals over others in the environment. Thereby, precise (expert) knowledge of the target characteristics (because of extensive experience with the search objects) can profoundly improve detection performance (e.g., ground-feeding birds like pigeons or chicks are highly efficient in detecting grains between pebbles; Fig. 1c). When the exact appearance of a search object is not known (e.g., when different edible grains or seed might be present on a ground), the individual can use characteristic visual properties, which are invariant across diverse members of an object class (**categorizing**).

At the beginning, parallel search gains a global impression of the scene eventually detecting critical features allocating attention to possible target objects while filtering out distractors and background noise. As a primary filter, several species display differential resolution of visual processing. The retinae of primates or many birds, for instance, possess areas of enhanced visual acuity (**fovea**) so that detailed vision is confined to a small range of the visual field while the rest is only diffusely perceived. This in turn requires attentional mechanisms guiding gaze to positions

in the visual scene that might contain the target and that should be analyzed more extensively. Eye movements are controlled by a mesencephalic brainstem network that is highly conserved in vertebrates with the optic tectum (superior colliculus in mammals) as a central structure that closely interact with specific forebrain areas in orienting gaze (Knudsen 2011).

Bottom-up and top-down processes converge to establish a **salience map**, which encodes conspicuous features while preserving topographic organization of the scene. This map is used by the gaze controlling networks to guide eye movements. Thereby, **salience** describes how distinct one element of a scene is from surrounding elements. Sometimes, a characteristic feature of the search object “pops-out” since it is very different from the surrounding (e.g., a ripe, red berry in green leaves). It automatically attracts attention and the object can be directly identified by parallel search. Many plants, which depend on animal pollination or seed spreading, harness this ability by vividly coloring their fruits and blossoms. Pop-out effects can be observed in different vertebrate species and even insects like bumblebees (Nityananda 2016), indicating that parallel analysis of features in a visual scene is a universal search mechanism across the animal kingdom. Salience can also be caused by a highly biological relevance of a stimulus (a predator hidden in the underwood). These stimuli are detected faster because of phylogenetically developed attentional priority mechanisms. Humans and other primates for instance detect deviant snake picture in a complex array more quickly than neutral stimuli like flowers (Shibasaki and Kawai 2009). Moreover, experience-dependent “**search images**” facilitate as primed representations the detection of vitally relevant objects. Foraging birds for instance overselect grain types that are relatively abundant. Tits, which capture different insect during flight, are more likely to notice that prey type, which they have repeatedly encountered before. In a similar way, honey bees typically restrict their search to a subset of available flower species when exploiting nectar and pollen sources on a meadow (**flower constancy**).

Understanding the structure of a scene also supports search since a natural environment exhibits regularities, which provide information about the likely localization of search objects (Le-Hoa Võ and Wolfe 2015). **Contextual cues** direct attention via top-down processes to those parts of a visual environment that have the highest probability of containing the target (ripe fruits are found on tree tops and not in the underwood). Knowledge increases with experience since individuals gain memory for the localization of detected targets in a familiar environment.

Parallel search identifies candidate objects or locations in space, which are selected for more detailed analysis during **serial search**. In this case, focal attention is allocated from object to object until the target is identified. Serial search is always necessary when a search item does not pop-out or when complexity of a search item requires combination of different features. Since combination of different features is computationally demanding, single objects can only be analyzed and recognized successively. The underlying neuronal processes represent key aspects of models of visual attention like the **Feature Integration Theory** of Treisman (Wolfe 2003). Detailed analysis and combination of features finally enables object recognition. This is a demanding computational process on its own and a prerequisite to initiate an adequate behavioral response.

Serial and parallel search might be controlled by processes in the left or right brain side. In several species, visual attention and hence search is not symmetric across the visual field. Chicks and pigeons for instance preferentially peck into the left visual half-field when they explore an area uniformly spread with grains. Since input from this half-field is processed by the right brain side, the leftward bias indicates right-hemispheric control of visuospatial attention (Diekamp et al. 2005). Since grains are not obscured under test conditions, parallel search enables quick collections of the food items. The underlying global processing is a typical specialization of the right brain side in vertebrates. When, however, grains have to be discriminated from similar looking pebbles (Fig. 1c), the left hemisphere is more

efficient in mediating a detailed analysis of visual stimuli requiring focused attention and serial search (Rogers 2017).

## Definition

Knowing what one's own appearance looks like.

## The Importance of Visual Self-Recognition

Although many of us experience seeing our own image on a daily basis (e.g., brushing our teeth using a mirror, catching our reflection in a window), we perhaps take our ability to know what we look like for granted. This seemingly mundane ability has nonetheless evoked substantial scientific, philosophical, and ethical interest. For example, self-recognition matters because it may be a proxy for complex psychological phenomena such as self-conception (i.e., a sense of identity persisting across time and space), self-awareness (i.e., making one's self the object of attention), and/or secondary representation (i.e., generating

and comparing multiple mental models) (see section “[Psychological Mechanisms](#)”). In turn, assuming that self-recognition indicates some form of psychological complexity has led to it being used as evidence in legal cases concerning “rights” for nonhuman primates. For instance, as yet unsuccessful bids to secure human rights for chimpanzees have been based at least in part to their ability for self-recognition (Gagneux et al. 2005). Nonetheless, evidence for self-recognition has successfully contributed to the prohibition of invasive great ape research in countries such as Japan, the Netherlands, the United Kingdom, Sweden, Germany, Austria, and New Zealand (e.g., Cavalieri and Singer 1994). Finally, self-recognition also matters because it may be the basis of our capacity to engage in effective image management (via monitoring and modifying what we look like) and recognizing our kin (via self-referent phenotype matching), both of which may contribute to enhanced reproductive success (see section “[Function](#)”; Butler et al. [to in preparation](#); Suddendorf and Butler 2013).

### How to Test for Visual Self-Recognition?

Despite the behavioral simplicity of self-recognition as a psychological construct (e.g., I can say “that is me” when looking at my own body or image), an objective way of measuring this ability in nonhumans (and human infants) remained elusive for many years (Butler 2015). Early attempts in the nineteenth century – including by Charles Darwin – consisted simply of reporting reactions such as surprise or aggression by monkeys and apes when presented with a mirror. Such reports are problematic because of the absence of any systematic, objective procedure; animals’ emotional responses to their own reflections are ultimately ambiguous, not least because of potential observer biases which may influence how such expressions are interpreted (Butler 2015). It was not until 1970 that Gordon Gallup published his seminal methodological breakthrough for overcoming such problems.

After observing that chimpanzees eventually ceased responding socially to their reflection and

used the mirrors instead to spontaneously engage in self-inspection and grooming of otherwise unseen body areas (inside their mouth, their anal-genital region, etc.), Gallup (1970) conducted what came to be known as the “mirror-mark test.” He found that chimpanzees with surreptitiously placed marks on their forehead and ears engaged in explicit self-directed responses toward these unfamiliar and otherwise non-visible marks, but only in the presence of a mirror. This simple procedure has since become the gold standard approach for investigating self-recognition in human infants and animals alike (see section “[Appropriate and Inappropriate Testing Procedures](#)”).

### Which Species Show Visual Self-Recognition?

Being a proxy for psychological complexity (i.e., self-awareness), some researchers continue seeking to simply determine which species do and do not show self-recognition. Numerous species have been tested for self-recognition *without* using the mirror-mark test, including fish, dogs, sea lions, killer and false killer whales, and various birds (Butler 2015; Butler et al. [to in preparation](#)). With the exception of possible contingency testing by whales, all of these species have either shown little interest in their reflection or reacted similarly to how they react toward an unfamiliar conspecific. More definitive evidence requires the mark test.

To date, only the great apes (i.e., humans, chimpanzees and bonobos, gorillas, orangutans) have shown replicated evidence for passing the mirror-mark test (and/or compelling evidence of spontaneous, mirror-guided self-exploration) (Butler 2015; Butler et al. [to in preparation](#)). It is important to acknowledge that for various reasons (e.g., differences in motivation and/or “passing” criteria), not all individuals pass the mark test or show spontaneous mirror-guided self-exploration (Swartz et al. 1999). Nonetheless, there is overwhelming evidence that all great ape species possess the ability for self-recognition. No equivalent evidence exists for other nonhuman primates,

including the small (or lesser) apes and numerous species of monkeys (Anderson and Gallup 2015; Butler 2015; Butler et al. *to in preparation*) (see Controversies).

Several non-primate species (including manta rays, horses, pandas, and even ants) have been tested for self-recognition using various adaptations of the mark test, with no convincing positive results (Butler et al. *to in preparation*). However, evidence for a few species remains contentious. For instance, one out of three Asian elephants passed the mark test but failed on a re-test (Plotnik et al. 2006), while two elephants showed no positive evidence in another study (Povinelli 1989). One out of two dolphins looked more at their marked than their unmarked image (Reiss and Marino 2001), but to date there has been no reported replication of this finding. Similarly, there has been no replication of the report that one killer whale removed a mark by rubbing itself against the pool wall (nor was there a comparison to a non-mirror baseline period) (Delfour and Marten 2001). More recently, in contrast to a few claims for self-recognition in some corvid species (Clary and Kelly 2016; Prior et al. 2008), other authors have reported negative findings (Soler et al. 2014). At best, claims for self-recognition in non-primates should be considered with caution pending methodologically rigorous replication (see section “*Appropriate and Inappropriate Testing Procedures*”; Gallup and Anderson 2018; Suddendorf and Butler 2013).

Testing for self-recognition in media other than mirrors warrants consideration, for at least two reasons. Firstly, from human studies we know that being able to recognize one’s own reflection does not guarantee self-recognition in non-mirror situations (i.e., some people can recognize themselves in mirrors but not videos or photographs and vice versa) (Butler 2015). Secondly, with few exceptions, neurological studies of self-recognition in humans involve presenting participants with photographs or videos rather than mirrors (Butler 2015). Evidence for self-recognition in nonhumans in media other than mirrors is scarce. Some descriptions of responses to videos exist for chimpanzees, gorillas, orangutans, some monkeys, and even dolphins, but in

the absence of mark tests, most of these reports are ambiguous at best (Butler 2015; Butler et al. *to in preparation*). There have only been two reported instances involving video mark tests, both providing positive evidence for self-recognition in chimpanzees (Hirata et al. 2017; Suddendorf et al. 2006). Evidence for self-recognition in pictures includes correct self-labeling by Koko the gorilla (Patterson 1978) and Ai the chimpanzee (Itakura 1992), and categorization by Viki the chimpanzee, who placed her own photograph in a “human” rather than “nonhuman” pile (despite placing her father’s photo in the latter) (Hayes and Nissen 1971). Although intriguing, such evidence requires replication and extension using complementary methodological approaches.

## The Evolution of Visual Self-Recognition

On the basis of replicated evidence involving great apes (see Fig. 1), we can consider two potential scenarios: either each individual species (i) independently evolved the capacity for self-recognition (i.e., convergent evolution occurred four or five times) or (ii) retained the capacity for self-recognition after it *originated only once* in a common great ape ancestor, between 14 and 18 million years ago (i.e., homologous evolution). This latter account – being the most parsimonious – is the strongest explanation for the current distribution of self-recognition (Suddendorf and Butler 2013). In the event of more compelling evidence concerning more distantly related non-primate species such as elephants, cetaceans, or corvids, additional explanations invoking convergent evolution will be required (see Future Challenges).

## Controversies

There are several contentious issues concerning self-recognition, including (i) appropriateness of testing procedures, (ii) psychological mechanisms, and (iii) function (i.e., whether self-recognition is adaptive).

**Visual Self-Recognition, Fig. 1** Distribution of visual self-recognition amongst primates (please note that these time frames are estimates)

### Appropriate and Inappropriate Testing Procedures

Given the prominence of the mark test for investigating self-recognition, it should come as no surprise that multiple variations have been reported – including both prior to and during the actual test (e.g., the amount of image exposure before testing; age at exposure; using mirrors that reduce eye contact; concave and convex mirrors; physically accessible mirrors; applying extra-salient marks such as chocolate or sugar icing; etc.) (Anderson and Gallup 2015). None of these variations have produced positive results for primates other than the great apes, although it should be noted that intriguing (and as yet, un-replicated) results were recently reported for a corvid species (Clark's nutcrackers) when using blurry rather than clear mirrors (the former being more akin to how birds may see themselves reflected in natural water sources) (Clary and Kelly 2016). Perhaps the most important modification to Gallup's original test involves the additional marking of visible rather than non-visible body regions (e.g., Gallup et al. 1980). If the subject responds to directly visible marks on an arm but ignores a mark on

the head that is visible only in the mirror, this rules out the possibility that the negative result for self-recognition is due to low motivation for any mark touching.

Some claims to have demonstrated self-recognition in monkeys and non-primate species deserve skepticism because of the questionable methods used. For example, the omission (or non-reporting) of a pre-image exposure control period following the initial marking of the subject means that tactile cues for any subsequent mark-directed behavior cannot be ruled out (Anderson and Gallup 2015). Similarly, some subjects have not been nescient while their appearance is altered; therefore, any subsequent image-mediated behavior may be nothing more than an artifact of stimulation such as tactile sensations from an area they know has been altered (e.g., head implants). Indeed, such a possibility has been verified: Soler et al. (2014) could not replicate previously reported positive results for self-recognition in corvids (using colored stickers as marks) once tactile cues were accounted for. Perhaps the most serious issue, however, concerns the use of operant conditioning to engineer

mirror-mediated self-directed responses ostensibly similar to those which occur *spontaneously* in great apes (Anderson and Gallup 2015). At best, subjects trained to pass the mark test only via hundreds (or thousands) of reinforced trials are simply showing something that superficially resembles self-recognition (much as a robot can be easily programmed to elicit a specific reaction toward an object using simple “if – then” rules without actually understanding what that object is). Recall, too, that Gallup’s original mark test was preceded by his observations of chimpanzee’s *spontaneous* mirror mediated self-inspection. In short, while conditioned training might result in self-recognition, it ultimately drains the mark test of its power to determine whether an organism really deserves allocation to the positive (“self”-possessing) side of the cognitive Rubicon (de Waal 2008). To remain as the “gold standard” for self-recognition, the mark test must be conducted carefully within behavioral contexts involving spontaneity and self-inspection.

### Psychological Mechanisms

Explanations for the psychological mechanisms underlying self-recognition fall along a continuum of cognitive complexity ranging from “lean” to “rich” (Suddendorf and Butler 2013). Prominent examples of the former include associative learning (i.e., contingent reinforcement as discussed above) (Epstein et al. 1981), distinguishing between internal versus external sources of information (i.e., self-recognition is simply a by-product of an ability for not bumping into things) (Heyes 1994), and kinesthetic-visual matching (i.e., matching the image of a moving body part with the contingent sensation of one’s own moving body part) (Mitchell 1997). Such accounts, respectively, fail to explain spontaneous manifestations of self-recognition, the limited distribution of self-recognition among species that are capable of not bumping into things, and why (in human infants at least) self-recognition emerges only approximately 12 months after contingency testing first occurs (Butler 2015; Suddendorf and Butler 2013). Psychological explanations for self-recognition require at least some representational complexity.

Gallup (1985) proposed the most prominent and rich account of self-recognition, arguing that it presupposes the existence of a self-concept, which in turn presupposes the existence of self-awareness (i.e., making one’s self the object of one’s own attention). Moreover, this self-awareness allows insight into one’s own mental states, which may then be utilized for knowing the mental states of others (i.e., theory of mind); self-awareness may even contribute toward awareness of one’s own eventual death. The evidence in support of Gallup’s view is mixed (Butler 2015; Butler et al. [to in preparation](#); Suddendorf and Butler 2013). For instance, infants who have passed the mark test go on to show evidence for (i) other forms of self-awareness (e.g., self-related emotions such as guilt, shame, and embarrassment), (ii) appropriate personal pronoun use, and (iii) theory of mind (including empathy and joint attention). It is noteworthy that chimpanzees are clearly capable of empathy and joint attention, and they also show at least some aspects of understanding death (Anderson 2016). However, complications arise. Firstly, if self-recognition presupposes the existence of a self-concept and a “broad” self-awareness, why are there dissociations involving self-recognition across media (i.e., human infants require an additional 12 and 24 months beyond mirror recognition to pass live and delayed video versions of the mark test)? One possible explanation is that those infants who first show mirror recognition have a limited form of self-conception restricted to the present (i.e., a basic “online” self-concept), while older children who pass video versions of the mark test possess a self-concept which extends through time and space (i.e., the self-concept “proper”) (Povinelli 2001; Povinelli et al. 1996). This explanation, however, fails to account for why infants who pass the mirror-mark test do not pass the live video version of the mark test. Moreover, despite the emergence of self-recognition in human infants during their second year, they retain limited capacities for understanding (i) the minds of others until age 3–4 years (when passing false belief tasks) and (ii) the biological characteristics of death until several years later (Suddendorf and Butler 2013, 2014).

Similarly, there is only limited evidence that chimpanzees or other great apes understand that others can have false beliefs or are aware of their own eventual death. In summary, while lean proposals do not go far enough, Gallup's rich proposal goes beyond the current evidence (Suddendorf and Butler 2013, 2014).

Several intermediate accounts have been proposed, at least for self-recognition in humans; for instance, self-recognition specifically requires being exposed to one's own face and the importance that others attribute to it (e.g., Niesser 1997). Such an explanation fails to account for the similar developmental trajectories in self-recognition based upon leg and face versions of the mark test (Nielsen et al. 2006). Perhaps language is somehow implicated? This is unlikely given that (a) human infants demonstrate rudimentary language abilities long before passing the mark test (c. 18–24 months) and (b) the vast majority of nonhuman great apes that have passed the mark test have not been trained in human “sign” language. Another intermediate account of self-recognition involves a domain-general capacity known as secondary representation (i.e., simultaneously generating and comparing multiple mental models about something). According to this account, self-recognition occurs when we can generate and compare representations of what we *think* we look like with what we *do* look like; in other words, we recognize what we look like because we are able to create, compare, and rapidly update mental models about our appearance (Suddendorf and Butler 2013, 2014). This need not involve a broad level of self-awareness as advocated by Gallup; it requires only an awareness of our own appearance (therefore making this proposal less “rich” than Gallup's). Evidence for the role of secondary representation in self-recognition is accruing: not only do human children tend to develop several other secondary representational abilities at around the same time (i.e., means-end reasoning, pretense, etc.), among primates, these same secondary representational abilities appear to be shared only with the other great apes (Nielsen and Dissanayake 2004; Suddendorf and Whiten 2001). This explanation – like Gallup's – struggles to account for

dissociations in self-recognition across different media, although this may reflect something to do with expectations involving the media used rather than differences in self-conception per se (i.e., unlike mirrors in which one can almost always expect to see their own image, video monitors are usually associated with seeing things other than one's own image). Nonetheless, secondary representation currently provides the best account for the development and distribution of self-recognition.

One crucial factor that most causal models of self-recognition have ignored is the role of affective processes and their regulation. To date, however, only the “dual-route” model of self-recognition – based upon clinical cases of misidentification – has attempted to integrate cognitive and affective processes (Breen et al. 2000; Butler 2015). According to this model, faces are structurally encoded (i.e., facial features are extracted and then holistically combined), after which the resulting representation is matched with previously stored representations (i.e., face recognition units). Information processing then occurs along two distinct cognitive and affective appraisal routes, with the former being responsible for overt recognition (retrieving semantic information) while the latter underlies covert (affective) recognition. Identification occurs when these appraisals are successfully integrated. This model of self-recognition is consistent with a secondary representational account, including the focus on expectations about one's appearance, but it remains to be investigated from ontogenetic and phylogenetic perspectives (Butler 2015). For example, do children or animals failing mark tests actually integrate expectations about what they should see *and* feel when looking in the mirror? What do chimpanzees *feel* when they see and recognize their own reflection or not?

## Function

While researchers have long considered self-recognition in relation to its evolution, development, and underlying mechanisms, the same cannot be said about whether this ability has any Darwinian value (Butler 2015; Suddendorf and Butler 2013). There is some consensus that

self-recognition likely originated in a common great ape ancestor as a *by-product* of another adaptive ability such as self-awareness or secondary representation; that is, self-recognition itself was not selected for but merely accompanied another adaptive trait (Butler et al. [to in preparation](#); Gallup 1997; Povinelli and Cant 1995; Suddendorf and Butler 2013). This has led to explanations focusing on the proposed adaptive trait from which self-recognition emerged, rather than on self-recognition per se. For instance, the clambering hypothesis (Povinelli and Cant 1995) posits that self-awareness was adaptive because it permitted a large-bodied, heavy, great ape common ancestor to safely navigate in its arboreal environment (by mentally monitoring and testing tree limbs during locomotion), thereby reducing the risks of serious injury from a fall; self-awareness thus increased the ancestral apes' chances of survival and reproducing. Although consistent with the almost exclusive arboreality of modern orangutans, this proposal struggles to account for the retention of self-awareness (and hence self-recognition) in less arboreal species, namely, gorillas, chimpanzees, and humans. Gallup (1997) subsequently proposed that a shift to ground-dwelling freed up self-awareness for use in understanding other individuals' minds, which was advantageous for meeting the complex cooperative and competitive challenges that characterized some great apes' social environments. An alternative account suggests that self-recognition originated as a by-product of another secondary representational ability (Suddendorf and Butler 2013; Suddendorf and Whiten 2001). This would be advantageous because secondary representation allows an organism to simultaneously represent and compare multiple mental models about things that may or may not actually exist, i.e., an individual can consider negative or positive outcomes for any situation, rather than having to actually experience them (Suddendorf and Whiten 2001).

Regardless of whether self-recognition originated as a by-product of self-awareness or secondary representation, it remains to be determined whether it has acquired any adaptive value in its own right. There are at least two scenarios for which this may be the case: image management

and self-referent phenotype matching (Butler et al. [to in preparation](#); Suddendorf and Butler 2013). The value of the former is that self-recognition allows for monitoring and modifying one's appearance, which may be important for multiple reasons including showing group membership, status, formidability, trustworthiness, etc. For example, evidence indicates that attractive people have several advantages including enhanced reproductive opportunities and success (for review, see Gangestad and Scheyd 2005). It follows, therefore, that knowing what one looks like facilitates modifying one's attractiveness, which in turn leads to enhanced Darwinian fitness. The advantages for self-referent phenotype matching, which involves identifying potential kin on the basis of how much they resemble one's own appearance, include avoiding inbreeding with close genetic relatives and being more prosocial toward those who share one's own genes (DeBruine 2005). Evidence for both of these functions is largely restricted to modern humans; it may extend back a few hundred thousand years in the case of image management (Butler et al. [to in preparation](#)). While there is "evidence of absence" for concern about one's own appearance in modern great apes, there is an "absence of evidence" for self-referent phenotype matching, although chimpanzees appear capable of phenotype matching in general, i.e., identifying potential relatives on the basis of how much they resemble their close kin (Parr and de Waal 1999). At present, it is difficult to know whether self-recognition has remained a mere by-product of another adaptive trait or has become a secondary adaptation, exaptation, or spandrel (Butler et al. [to in preparation](#)).

## Future Challenges

Much has been learned about self-recognition in the half-century since Gallup's (1970) pioneering study. However, important gaps within the comparative literature remain, many of which have been identified above (e.g., the need for replicating findings in elephants, cetaceans, and birds; using more tests based on other media; and testing

for image-management and self-referent phenotype matching or any other possible function). In addition, while researchers have started to address the comparative neuroscience of self-recognition (Butler and Suddendorf 2014; Hecht et al. 2017), much more is needed. Not only would this improve psychological explanations of self-recognition (e.g., determining the relative involvement of emotional versus cognitive brain areas), it would shed light on whether this ability is an adaptation, exaptation, spandrel, or mere by-product (just as understanding morphological differences in bird feathers has led to explanations about some feathers being originally adaptive for thermoregulation prior to becoming a secondary adaptation for flight). Similar possibilities exist for genetics research, with only one chimpanzee study published to date (Mahovetz et al. 2016). Social factors also warrant further attention, for example, determining possible influences of enculturation and maternal styles on manifestations of self-recognition (Anderson and Gallup 2015). Finally, and perhaps most importantly, while it is important that tests of self-recognition are ecologically valid for the species in question (e.g., Clary and Kelly 2016), scholars must strive for methodological rigor in designing studies to ensure that well established best practices (e.g., comparing mirror-mediated mark touches versus a pre-mirror control and non-marked areas) are not ignored.

## Waist-Hip Ratio

Vivek Kumar  
Department of Biotechnology, IMS Engineering  
College, Ghaziabad, India

## Synonyms

[Waist to hip ratio](#)

## Definition

It is the ratio of perimeter of waist to the hip.

## Waist-Hip Ratio

Fat is one of the most important constituent of diet. However, fat deposition in the body could be

harmful to health among all the people irrespective of age, sex, and ethnicity. Fat tends to deposit in abdomen and hip than any other place in the body, for both male and females. Waist-hip ratio is a significant health parameter, and it relates with serious health problems. Waist-hip ratio describes distribution of harmful fat around abdominal region (visceral fat). Overweight and obesity are often found to be related to major human disorders responsible for several deaths worldwide like diabetes, hypertension, heart diseases, and several other disorders (Emery et al. 1993).

Nowadays, doctors consider waist-hip ratio along with body mass index (BMI) for determining fat distribution. Some consider it as better parameter than BMI (as it fails to predict body fat distribution), which otherwise do not distinguish contribution of fat and muscle mass (person with athletic body with very low body fat content can have high BMI). Waist-hip ratio focuses on central obesity specifically which is more related to metabolic disorders (Emery et al. 1993).

## Determining Waist-Hip Ratio

To calculate waist-hip ratio, a person should measure waist just above the belly button and hips should be measured around the widest part. Measurement can either be made in cm and inches. This ratio helps in classifying body shapes, namely apple (people with tendency to accumulate fat around abdominal region) and pear

(people with tendency to accumulate fat around hip region). Doctors consider apple shape body to be at higher risk of developing metabolic disorders (WHO Report).

## Waist-Hip Ratio and Health

Waist-hip ratio is not only a good indicator of common metabolic disorders but it has been reported to be related with various other conditions as well. Value of waist-hip ratio means differently for different gender as both men and women accumulate body fat differently. For women, waist-hip ratio of 0.80 is considered as low health risk, ratio between 0.81 and 0.84 indicates moderate risk, and value above 0.85 indicates high risk. For men, waist-hip ratio of 0.5 or below is considered low health risk, 0.96–0.99 as moderate, and waist-hip ratio value of 1.0 or above indicates high risk. However, some exceptions are there to waist-hip ratio values; some medical conditions are known to cause higher fat deposition around abdominal region. Also some ethnic groups are exception to this as well (WHO Report).

Waist to hip ratio is related to type II diabetes and cardiovascular diseases in both males and females, many study consistently report higher ratios to be risk factor of this disorder (Qiao and Nyamdorj 2010). Studies also suggest that it is also a good predictor of heart diseases (Streng et al. 2018).

Waist-hip ratio is also reported to be important health predictor for elderly men and women. A study reported it as a good predictor of elder mortality (above 75 years) as compared with BMI (Price et al. 2006).

## Waist-Hip Ratio and Human Attractiveness

Research indicate that optimal waist-hip ratio is also related to attractiveness in both males and females; it is suggested that optimal ratio is associated with optimal sex hormone level which is related to higher fertility and lower risk of

disorders related to these hormones. A study indicated that ratio of 0.8 in males is related to enhanced male attractiveness (Fan et al. 2005). Females with lower ratio also found to enhance female attractiveness (Henss 2000). Optimal waist-hip ratio in both genders are found to relate to better health; in women, lower ratio relates with lower risk of ovarian cancer; in males, it relates with lower risk of cancer of prostate and testes (Singh 2002; Boehm et al. 2015).

## Conclusion

Waist-hip ratio is a good parameter to understand distribution of fat in the body and how it affects the health. In near future, it is expected to gain acceptability equivalent to BMI among doctors and common people.

## Warning

Nicola Marples  
Trinity College Dublin, Dublin, Ireland

## Synonyms

[Aposematism](#); [Warning coloration](#)

## Definition

Warning is the state of being warned. A warned individual uses conspicuous signals, often colors, which indicate to a predator or a competitor that it is not profitable as a prey item or it is alert. In the case of unprofitability, it is often due to the presence of toxic chemical defenses but could be achieved in a large number of ways such as speed, toughness, or by carrying spines (Ruxton et al. 2004).

## Introduction

Warning in the animal kingdom takes a number of forms, which can be considered under the different modalities in which they occur, or they may use a combination of modalities.

The most commonly recognized modality for warning signals is probably visual signals such as aposematic patterns and colors (see entry on aposematic signals, and also below as aposematic signals are usually multimodal), visible spines or hairs, or movements which warn the receiver of the danger or unprofitability of approaching the signaller any further. Some alarm signals would be included in this visual category, with movements such as stotting in gazelles (reference) and tail flicking in deer (reference) indicating to their conspecifics that a predator is near but also indicating to the predator that it has been spotted and therefore would not benefit by pursuing the attack further. Warning movements would also include threat displays (see entry for threat displays) such as baring teeth and raising of hackles in dogs (reference) and charging at the enemy as seen in rhino, buffalo, and bulls (reference). Displacement attacks may also be seen in some animals, including humans (reference), where the attack is aimed at an inanimate object as a warning of what force is likely to be available to be exerted on the opponent should the attack be followed through. The visual warning may even be dishonest, as is present in a startle display, when typically an insect puffs itself up and displays a pattern which resembles eyes, making itself appear to be the head of a snake, or a much larger organism, in an attempt to frighten the predator off (reference).

The next common modality for warning would be warning sounds or calls. Many insects and other small potential prey items such as the death's head hawkmoth make a sound when attacked, to attempt to startle the predator into letting them escape (reference). Others which do have a defense such as rattle snakes have a warning rattle, and bumblebees give a specific warning buzz, alerting the predator to the presence of the defense. Similarly the howls of wolves and roars of lions warn potential rivals of the size of the group defending that territory and some indication of its strength. Many alarm calls are not visual signals, such as Belding's ground squirrel's calls warning of approaching enemies and birds giving hawk alarms. In some species these calls can be predator-type specific, so vervet monkeys,

meerkats, and chickens all give a different call according to whether the predator is a ground predator or an aerial one, and vervets also distinguish a snake category (reference). It could be argued that all bird territorial songs are warning in function, informing rivals of the presence of a male prepared to fight to maintain ownership of that territory, as well as acting as an honest signal by which females can select a good mate.

Warning odors tend to be less commonly observed, partly through lack of work on them, but also because they tend to travel less far, exposing the attacked animal to the close proximity of the attacker before they can be detected. Skunks, ants, and bombardier beetles get round this by spraying the warning odor at the attacker. Warning odors include pyrazines, which are thought to have an “alerting” function, increasing the effectiveness of predator learning (reference). These are often found in aposematically defended organisms (see below).

Finally warning tastes are a matter of some debate. Some authors consider distastefulness to be a defense in itself, while others consider chemicals which confer a taste but have no toxic function to be warning tastes (references). These are often bitter, resembling the taste of the toxins in many defended species.

In some defensive systems, such as aposematism, multiple warning signals are given at the same time, often in different modalities (reference). These “multimodal” warning signals have been the subject of extensive research, and so this system is discussed below as a classic warning complex.

## The Principle

Originally described as “warning colouration” by Alfred Russel Wallace, the concept of an organism advertising its unprofitability as prey by displaying a warning signal was redefined by Poulton (1890) as “aposematism” (from Greek *ἀπό* *apo* away, *σημα* *sema* sign). Both terms have survived in the literature and are used interchangeably to describe a range of antipredator adaptations united by the presence of a signal

indicating that the prey is unprofitable to eat. Aposematism relies on the predator noticing a prey’s appearance, learning through a bad experience that eating that prey is detrimental, recognizing the prey the next time it is encountered, and avoiding attempting to eat it. The signal is much more effective at causing this learning and recall if it is conspicuous, so organisms employing aposematic defenses are selected to be conspicuous. Therefore there is an intrinsic cost to aposematism, since naïve predators, which are unaware of the meaning of the signal, will attack and attempt to eat these conspicuously signaling individuals until the predator has had enough experience to learn to avoid them.

## The Signal

The signal used often includes a conspicuous pattern of colors, with internal contrast provided by the use of red, yellow, or white contrasting against black, often in the form of spots or stripes. However a wide variety of patterns can be found, with the emphasis being on easy detection and recognition. A color pattern is only one possible signal and is often replaced or augmented by specific odors, tastes, sounds, and movements all of which are adapted to increase conspicuousness and memorability. One particular odor, pyrazine, was postulated by Rothschild to be an “alerting” signal, making the predator more aware and able to learn the meaning of the warning color (Rothschild and Moore 1987). Pyrazine odor is present in many insects (Moore et al. 1990) and has now been shown to be more effective in enhancing learned avoidance than other odors (Marples and Roper 1996). Even sounds, such as the buzzing of angry bumblebees, can augment a visual signal to increase its effectiveness (Siddall and Marples 2011). The use of several signals together, referred to as “multimodal signalling,” is more effective than single cues at promoting both the predator’s learning (Marples et al. 1994; Siddall and Marples 2008) and memory (Marples et al. 1994; Siddall and Marples 2008) of the encounter. Aggregation can further strengthen the learning of the signal (Riipi et al.

2001) by offering a large, even more conspicuous cue, with the signal repeated many times, and still visible to the predator even if one of the prey are consumed. Aversive taste, or unpalatability, is often considered to be part of the defense of aposematic animals, but it is actually part of the signal. As long as the chemical conferring the unpleasant taste is not toxic (i.e., it has no physiologically detrimental effect on the predator), there is no adaptive benefit for the predator to avoid bad tastes, other than their frequent association with unprofitable prey. However tastes can signal the presence of a second, toxic chemical, just as other signals can.

### Unprofitability

The defenses of aposematic or warningly colored prey have long been described in terms of chemical toxins making the prey aversive to the predator (Poulton 1890; Rothschild and Moore 1987). Such toxins are either manufactured by the defended organism itself or may be sequestered from its food. They are sometimes stored in specific organs such as the nematocysts in jellyfish or the sting of a bee. Alternatively they may be spread throughout the skin (e.g., dart-poison frogs) or be present in the hemolymph of an insect (heliconius butterflies) or may be manufactured only on attack (e.g., bombardier beetles). Toxic chemicals are however not the only form in which an effective defense can be mounted. The only necessity for aposematism to work is that pursuit and consumption of the prey should not be worth the predator's while; in other words, it should reduce the predator's fitness; it should be unprofitable. Any feature of the prey which makes it unprofitable will mean that it is adaptive for the predator to avoid that prey type, and so advertising this by means of conspicuous becomes adaptive for the prey, i.e., it can use warning coloration. So while most aposematic organisms are advertising that they contain a toxin, there are others which advertise that they are hard to handle, fast at escaping, tough bodied, indigestible, or otherwise not easy to catch, handle, or eat (Ruxton et al. 2004).

### Mimicry

As stated above, aposematic organisms pay a price for their protection in that they must run the risk of meeting a naïve predator and being the individual which dies teaching the predator what their conspicuous signal means. They can dilute this risk, as well as enhance the effectiveness of their signal by aggregating together with others of their own species. They can further dilute the risk by using the same signal as others defended prey of other species. This sharing of the same signal between defended species is called "Mullerian Mimicry," first described by Fritz Muller (Müller 1878). Groups of species converge on the same signal to form what is referred to as a "Mullerian Mimicry Ring," examples being several species of red and black ladybirds, and bumblebees and wasps which share black and yellow-striped patterns. There are also Mullerian mimicry rings in other modalities, for instance, snakes share auditory signals of hissing and bumblebees share their buzz signal. This convergence of signals is beneficial both to the aposematic species sharing the costs of teaching predators and to the predators themselves as they have fewer signals to learn so will have to suffer detrimental prey on fewer occasions.

Another sort of mimicry is commonly found, where the organism mimics the signal of an aposematic species but does not carry any toxin or other defense, and indeed is a profitable prey type. This type of mimicry was recognized by Henry Walter Bates (Bates 1861) and undermines the effectiveness of the aposematic signalling system. If one of these "Batesian mimics" is attacked by a naïve bird, the bird will get a good meal and consequently will learn that the color pattern indicates good food. The Mullerian mimics sharing that signal will then be attacked by this incorrectly educated predator, and as relearning is usually slower than learning from naïve, more unprofitable prey will be eaten before the predator is reeducated. This is therefore detrimental both to the aposematic populations and to the predators. One consequence of this is that Batesian mimics must remain rare compared to the aposematic prey they resemble. If the Batesian mimics become too

numerous, even locally, they destroy the very signalling system on which they rely for their defense. Therefore Batesian mimics avoid aggregation. They also tend toward polymorphism, in which there is more than one color pattern represented in the same species' population. Polymorphism allows the species to have some individuals parasitizing one aposematic color pattern and the rest of the population parasitizing another. A probable example of this is shown by the two-spot ladybird *Adalia bipunctata*, which has been shown to carry no effective chemical defense (Marples 1993a; Marples et al. 1989) and which has two different color patterns: a primarily red pattern with black spots resembling the well-defended seven-spot ladybird *Coccinella septempunctata* and a primarily black one with red spots resembling the defended Pine ladybird *Exochomus quadripustulatus* (Marples 1993b).

The distinction between prey species being Mullerian or Batesian mimics is not absolute, since the amount of toxin in an individual of an aposematic species may vary, and the susceptibility of different predators to being poisoned by a given level of toxicity may also vary, even within the same predator species. This has the effect that a particular prey item may be a Mullerian mimic to one predator individual, because it is unprofitable for that predator to eat the prey, but a Batesian mimic to another predator individual, because the second predator gains more by eating it than it loses through the effects of the toxin, i.e., it is a profitable prey (Speed 1999; Turner and Speed 2001).

## Evolutionary Paradoxes

The original evolution of aposematism has long been considered a paradox. This is because aposematic defenses only work when the majority of predators understand the meaning of the signal and all predators would be naïve when the trait first evolved. This means that the first individual prey item to develop a toxic defense and a conspicuous color pattern would have attracted attention from a predator, which would have eaten it. This might have taught the predator to avoid that specific color pattern, but as only one

individual carried the trait, and that individual has died educating the predator, the aposematic trait would have died out before it could get going. There have been a number of postulated solutions to this paradox, most of which are not yet supported by empirical evidence. One of the few explanations supported by both theoretical modeling (Lee et al. 2010) and experimental evidence (Thomas et al. 2003; Marples et al. 2005) is that arising from the action of dietary conservatism. It has been shown that part of the population of any species of fish and birds yet tested is fussy about their food, eating only familiar food types if given any option to do so (Marples et al. 1998). This fussy eating strategy is called "dietary conservatism" (DC), and it causes predators which are displaying the DC foraging strategy to avoid novel foods. If the first aposematic prey arose in the territory of a DC predator, then it would be avoided by that predator simply due to looking novel and could increase locally in numbers. The argument is that this would allow the aposematic trait to become common enough to train the local predators to avoid the aposematic signal and to get over the initial low-number paradox.

There is also evidence that some species have unlearned avoidance of certain conspicuous colors and patterns (Roper and Cook 1989) such as black and yellow stripes. This would reduce the likelihood of a new aposematic individual bearing this signal being eaten. However the order of evolutionary events is not clear, and there is always the possibility that the innate avoidance of these conspicuous patterns is actually an effect of the existence of aposematism. In other words predators may have evolved to hard wire an avoidance of yellow and black stripes because of all the aposematic animals which use this signal, in which case the innate avoidance could not predate and assist the initial evolution of aposematism.

However it survived the initial stages, once the population of aposematic individuals was large enough to educate the local predators into avoiding similarly signalling prey, there would be a selection pressure for other species to converge on the same pattern, and the mutually beneficial signalling system would persist and spread. Prey species would be selected to show a clearer and more memorable signal, augmenting it with

other signals to make a multimodal signal as conspicuous and recognizable as possible. A niche for cheating on this signal would open up and give rise to Batesian mimics, selected to copy the signal in each modality as accurately as possible. Predators would be selected to become better at learning and remembering the signal but also distinguishing between the Batesian mimics and the truly aposematic prey types. This coevolutionary system would be expected to drive all patterns toward the same, maximally memorable pattern.

This gives rise to one final paradox observed in this system. In reality many families of closely related aposematic organisms do not in fact share the same pattern. For instance, there are at least three different Mullerian mimicry rings of ladybirds present in Europe, each set of species bearing spots but one based on a red background, one on a black background, and one on a yellow background. Similarly in South America, there are multiple color patterns among the well-defended heliconius butterflies. What prevents the converging on the same patterns is unclear and continues to be one of the unanswered evolutionary paradoxes. It seems likely that the Batesian mimics undermining each signal would eventually make it beneficial to found a different Mullerian mimicry ring with a new pattern unparasitized by Batesian mimics. However the empirical testing of this idea would involve knowing which species in each ring were truly unprofitable to each of the local predators and which were profitable Batesian mimics. This degree of detailed knowledge is absent as yet from most of these larger and more complex mimicry systems.

## Washoe

J. Quentin Davis<sup>1</sup>, Heidi L. Shaw<sup>2</sup> and Mary K. Radeke<sup>3</sup>

<sup>1</sup>Augusta University, Augusta, GA, USA

<sup>2</sup>Yakima Valley College, Yakima, WA, USA

<sup>3</sup>Central Washington University, Ellensburg, WA, USA

## Introduction

Washoe became famous in the late 1960s for being the first nonhuman to use a human language, namely, American Sign Language (ASL).

Born in the wild in West Africa, Washoe was captured and eventually brought to the United States where she was acquired by the US Air Force. On June 26, 1966, however, her life was again redirected as Drs. R. Allen and Beatrix T. Gardner brought the infant chimpanzee to Reno, Nevada, to serve as a research subject in their cross-fostering laboratory. They named her Washoe *Pan satyrus*. Her first name came from Washoe County, the location of the University of Nevada, where the Gardners both taught in the Department of Psychology. Her middle and surnames (*Pan satyrus*) were, in 1966, the genus and species name for chimpanzees (now *Pan troglodytes*). Two weeks after arrival, Washoe had begun responding appropriately to the sign for COME, and within 6 months, Washoe was using signs spontaneously and in appropriate contexts (Gardner et al. 1989b). Washoe passed away in 2007 at the age of 42 having become one of the most well-known chimpanzees in history.

## Cross-Fostering with Chimpanzees

Cross-fostering is a research design commonly used by ethologists, comparative psychologists, and biologists to address the age-old nature-nurture question: What is the relative influence of environment and biology on behavior and traits? Researchers using this design typically raise the young of one species in the environment of and by adults of another species. They hypothesize that when these young exhibit behavior typical of the adoptive parents (and unlike that of the biological parents), the behavior is due primarily to learning acquired in the rearing environment.

Prior to Washoe, three other chimpanzees had been cross-fostered in human environments: Viki (Hayes and Hayes 1951), Gua (Kellogg and Kellogg 1933), and Joni (Ladygina-Kohts and de Wall 1935/2002). Each of these other chimpanzees lived in a home with adults who used spoken language and each readily learned human behaviors such as using a telephone, waving goodbye, dusting, turning lights on and off, drawing with pencils and crayons, etc. (e.g., Hayes 1951). Of the three, only Viki developed a spoken

vocabulary, and after almost 7 years and substantive training, she spoke only four words. However, in the mid-1960s when the Gardners were developing their protocols, Jane Goodall was reporting that, under natural circumstances, chimpanzees readily gesture to one another (1968). Also in the mid-1960s, most American children grew up in homes with a single language. The Gardners chose a single, manual language, ASL, for their project. In fact, they established a sign-only rule which precluded members of the research team from signing and speaking at the same time. With the addition of this naturally occurring, manual human language, and the strict sign-only policy, Washoe's cross-fostering environment was even closer to the environment of a typical human infant than previous cross-fostering projects of Hayes and Hayes, Kellogg and Kellogg, or Kohts. The Gardners' first cross-fostering project became known as Project Washoe.

### Project Washoe: The Early Years

Washoe's daily life in this cross-fostering laboratory looked remarkably similar to the daily life of a human child of the same age. To begin with, Washoe had a nuclear family unit consisting of Allen and Beatrix Gardner and a small group of other adult caregivers. She was accompanied by at least one of her family members every waking moment. Washoe's home was a trailer in the Gardners' backyard in a neighborhood of Reno, NV. Her home was equipped with a kitchen, bedroom, dining table (and high chair), toys, books, and bathroom. The Gardners modeled Washoe's daily routine (e.g., meals, naps, and baths) after routines common for human infants. Washoe wore the same sorts of pants and shirts and played with the same sorts of dolls and toys as human children her age. She ate the same sorts of baby food and graduated to the same sorts of meals as human children. She rode in wagons and cars, climbed trees, and went out for ice cream. In this cross-fostering laboratory, Washoe learned to use and flush the toilet and wash her hands afterwards. She engaged in school activities appropriate to her age, such as stacking blocks, stringing beads, and

coloring. She learned to use adult tools, such as weeding tools, brooms, dustpans, and mops. As she got older, she completed chores, like putting her toys away and taking her dishes to the sink by herself.

Throughout all of these daily activities Washoe's family members chatted with each other in ASL similarly to the way human adults do with their own infants, whether the language is spoken or signed. Along with caring for the young chimpanzee, the research staff of Project Washoe made meticulous records of Washoe's daily life, which included measures of her food intake, weight, development milestones, potty successes and accidents, communicative gestures, and her use of the signs of ASL, much of which can be seen in the films *Teaching Sign Language to the Chimpanzee, Washoe* (Gardner and Gardner 1973) or *The First Signs of Washoe* (Campbell-Jones 1974). In this setting, Washoe learned to communicate through signs about the world around her utilizing both concrete and abstract concepts such as BIRD, PANTS, TREE, DRINK, KNIFE, RED, OUT, QUIET, TELEPHONE, HEAR, GO, and FUNNY. Mistakes in sign form or grammar were corrected by the human family members. She signed to herself, to her human playmates, to toys and dolls, and to other animals.

### Adulthood

In 1970, at the age of 5, Washoe moved to the University of Oklahoma with Dr. Roger and Debbie Fouts and gradually entered a phase of more permanent captivity living among other chimpanzees. She remained in frequent contact with signing human family members and signed to the new chimpanzees' playmates as well (Fouts 1997; Fouts, Fouts and Van Cantfort 1989). She had two infants, both of whom died in infancy, and she later adopted a 10-month-old male chimpanzee, Loulis, acquired by Fouts from Yerkes. A second cross-fostering project initiated by the Gardners to replicate the findings of Project Washoe and improve upon the research methodology included chimpanzees Moja, Tatu, and Dar

(see Gardner et al. 1989b). These chimpanzees along with Loulis became Washoe's new adopted family. Between 1980 and 1981 the Fouts moved Washoe, Loulis, Moja, Dar, and Tatu to Central Washington University and later founded the Chimpanzee and Human Communication Institute (CHCI), a sanctuary and behavioral research facility on the university campus. Washoe's adoption of Loulis began a functional third phase of the signing research with chimpanzees. Like the others, Loulis also acquired signs of ASL, but not from human caregivers. With the exception of seven specific signs, all signing by humans was forbidden in his presence so that any additional signs learned would come from Washoe and the other chimpanzees (see Fouts, Fouts and Van Cantfort 1989). Washoe molded Loulis' hands into signs and modeled signs for him in context just as was done with her and as is done by deaf parents with their children (Fouts, Fouts and Van Cantfort 1989). The transmission of human signs from one non-human to another nonhuman was another groundbreaking discovery. After many years of contribution to research, in 2002 Moja passed away and in 2007 Washoe passed away. Following the death of Dar in 2012, in 2013 the remaining chimpanzee family members, Tatu and Loulis, moved to the Fauna Foundation in Montreal, Quebec. Since the closure of CHCI, researchers continue to analyze behavioral and signing records of Washoe and the other chimpanzees from their years in the cross-fostering laboratory through adulthood.

### Method Matters: A Response to Critics

Because of the Gardner's work with Washoe and other studies with similar aims, ape language research was a hot topic that was nationally funded in the 1970s and 1980s. Along with the research came plenty debate of methodologies and outcomes. A well-known critic of Project Washoe, Herb Terrace, claimed that Washoe's signs were primarily trained through the use of Skinnerian reinforcement and imitations of human caregiver signs. Others claimed that

apes could not sign without manipulation and coercion (Seidenberg and Petitto 1979). An abundance of research however provided evidence to the contrary. Washoe's signing was tested under rigorous double-blind controls early on though. The question of human cueing or imitation was resolved with Washoe's accuracy rate for reliably naming objects without the possibility of human influence; it was substantially greater than chance (Gardner and Gardner 1989). Additionally experimental controls were put in place to ensure that Washoe was identifying concepts rather than simple exemplars. Remote video recording of Washoe using the signs of ASL in the absence of her human caregivers (e.g., signing to herself about objects in her bedroom) provided further evidence of spontaneous and appropriate sign usage (Gardner and Gardner 1989). The Gardners furthermore explained that reinforcement actually hindered Washoe's signing much like the depressed productivity of children in response to external rewards (Gardner and Gardner 1989).

### Similarities with Human Language

The process by which Washoe and other cross-fostered chimpanzees learned signs was primarily through modeling and molding the chimpanzees' hands in the appropriate context for the sign (Gardner et al. 1989a; Fouts 1972). Fouts in fact even attempted imitation as a means of teaching signs to Washoe but with very little success in comparison to the techniques that are most similar to how deaf children learn ASL, molding and modeling (Fouts 1972). This research all but ended attempts to use Skinnerian reinforcement and imitation with Washoe and provided further evidence of the importance of the home environment, particularly natural conversation, as a factor in Washoe's signing record.

As with human children, Washoe's vocabulary was largely related to and dependent upon her experiences and the people with whom she signed. During her 51 months living under cross-fostering conditions, Washoe acquired at least 132 reliable signs (Gardner and Gardner 1989)

and many more that had not yet met the stringent requirements to be included in the vocabulary. Her vocabulary grew as she was exposed to new situations and new people reaching over 250 signs at the time of her death. Washoe's repertoire included signs from the categories of nouns, proper nouns, objects, attributes, verbs, markers, and locatives. Tatu, Dar, and Moja's vocabularies were equally as diverse, and Moja additionally had several quantitative signs (VanCantfort et al.). Washoe, Tatu, Moja and Dar often combined signs to describe a novel item or situation. Several unique combinations Washoe created included WATER BIRD for swans, CRY HURT FOOD for radishes, and LISTEN DRINK for Alka-Seltzer (Gardner et al. 1989a).

Other aspects of Washoe's development also resembled human developmental trends. For example, when she had acquired eight signs, she began combining them into phrases. As an infant she used childish forms of signs like signing on her caregivers and using simplified hand configurations (Gardner et al. 1989a). The development of object permanence in the second year was also shown to be comparable to that of human children in both sequence and rate of acquisition (Wood et al. 1980).

Further research showed that vocabulary and utterance growth by Washoe as well as Tatu, Moja, and Dar were remarkably similar to human children. They have been shown to respond appropriately and with various categories of signs contingent upon the type of Wh-question posed (Jensvold and Gardner 2000). Perspective taking was insinuated in research by Bodamer and Gardner (2002); when a human was not looking at the chimpanzees, they initiated interactions with attention getting sounds including noisy signs, but not silent signs. However, once the human was oriented and looking toward them, they used silent signs. Other studies of pragmatic abilities show that Washoe and her family used eye gaze similarly to deaf signers in conversation (Shaw 2001) and that they took turns in patterns similar to humans, engaging in much more interruptive overlap as infants than as adults (Hartmann 2011).

## Summary

Project Washoe and the subsequent projects described here were historical in that the Gardners largely replicated the rich social environment in which deaf children learn their native language to determine whether this would afford a chimpanzee the opportunity to acquire signs of ASL. Employing a manual language to communicate with a gesturing nonhuman species was a novel and successful approach to addressing research questions previously investigated by Hayes et al. The work that followed produced decades of research recording developmental and communicative behaviors of cross-fostered chimpanzees.

Hydroregulation

## Introduction

The term *water balance* as it applies to animals is an important aspect of physiology that reflects the principle embodied in “input-output” rules. In context of water balance, this stipulates that over time the input of water to an organism must equal the output of water if the body water content is to remain constant. Hence, the water lost must be replaced, and if excess water is ingested, it must be eliminated if the animal is to remain in “balance.” Water (as well as energy) is a fundamental requirement of living organisms and provides the milieu in which molecular reactions occur to maintain the processes of life. Hence, with the exception of transient “anhydrobiosis” (life with nearly complete drying) observed in certain invertebrates and seeds of plants (Alpert 2006), water is a central requirement for normal levels of metabolism, nutritional status, reproduction, and survival of organisms.

Water balance is an important underpinning to the behaviors of animals, and vertebrates are especially sensitive to dehydration and changes in behavior related to water resources (McNab 2002; Lillywhite 2016). In order to survive, animals must have sensitivity to water resources and the moisture conditions of their environment, and they must discriminate to some degree the quality of water in which they live or interact. Remarkably, although the sensory capabilities of animals related to water are central to survival, they have not been well studied. Animals must decide questions such as: To where should one disperse or migrate when water resources are depleted during drought? Where should one oviposit eggs such that the moisture quality of soil or nest is appropriate to development and hatching? What osmolarity of water is appropriate to ingest for an animal living in or at an estuary? How long should one continue to forage when dry conditions increase evaporative water losses? What properties of soil are appropriate or safe for burrowing animals that are sensitive to cutaneous water loss?

## Pathways and Processes of Water Exchange

Animals gain or lose water through various pathways that are depicted in Fig. 1. In summary, water is gained by animals via drinking, food, and in particular cases, absorption across the skin; water is lost from organisms in urine, feces, and evaporation involving the skin and any exposed mucous membranes including those contacting the ventilatory flow of air in and out of the lung during breathing. Various adaptations have evolved to limit losses in dry environments, and to adjust input-output in mesic environments. Over time, water balance requires that water inputs compensate for outputs or losses.

Water inputs to an animal generally involve drinking in addition to free water that is contained in food. Excess water is excreted from the body, and in vertebrate animals this involves the kidney. Depending on the species and the circumstance, water can be in excess or in deficit, and the excretory organ (kidney) responds accordingly. The kidney (usually paired structures) functions by filtering blood and modifying the resulting filtrate according to needs of the animal. Some substances are reabsorbed back into the bloodstream across the mucosa of kidney tubules, and other substances in need of excretion are secreted by

transporters across the tubular membranes and added to that already present in the filtrate. Water, of course, comprises a large percentage of the filtrate and can be added or subtracted, but only by passive means induced by osmotic gradients acting across membranes. The relative concentrations of solutes are adjusted by this means. The final filtrate is called urine and in many vertebrates can be stored temporarily in a structure called the bladder.

The kidneys of birds and mammals have specialized loop-like tubules that provide a means of concentrating urine. Without detailing the mechanism (which is described in any standard physiology or comparative physiology textbook), a dilute urine is produced if water is in excess supply, or a concentrated urine is produced if water is in short supply. The concentration of the urine is “adjusted” according to need by means of osmoregulatory hormones that are released from the central nervous system and act on the tubular membranes of the kidney to affect both transporters of salts and the permeability of tubular membranes where urine flows through regions of high salt concentrations surrounding the relatively elongated “loops” to produce the final urine product. Other vertebrates lacking such loops cannot produce a concentrated urine and conserve water by other means. Many amphibians living in water

### Water Balance,

**Fig. 1** Pathways for gains or losses of water from a tree frog (*Smilisca baudinii*) (Photograph by author)

or very wet environments produce a copious and dilute urine to remove excess water that continually “floods” the animal by osmotic movement across water-permeable skin. On the other hand, marine mammals have specialized kidneys that enable them to produce a concentrated urine and eliminate salts that invade the body during consumption of food. Reptiles living in marine or dry environments where conservation of water is important have other means of excreting salts and wastes in addition to the kidneys, which cannot produce a concentrated urine. These vertebrates – as well as certain birds living in dry environments or close association with seawater – possess *salt glands*, which are specialized organs capable of excreting high concentrations of salts with minimal water loss. These glands are accessory to the kidneys and are located near the eyes, nasal passages, or tongue in various species living either in dry deserts or marine environments where fresh water is scarce.

It is important to understand that excretory organs such as kidneys or salt glands can serve only a negative role in water balance. Urine (or secretions from salt glands) can vary in the concentration of solutes which it carries, but necessarily variable amounts of water are also removed from the body during the excretion of salts. Excretory organs do not add any water to the body, so the positive side of water balance requires sources of input in addition to whatever adaptations are present for conserving water.

## Inputs of Water

Animals have three sources of water. These are (1) dietary water, which refers to free water that is contained in the foods animals eat; (2) metabolic water that is a by-product of cellular metabolism, produced in relatively small amounts along with  $\text{CO}_2$ ; and (3) free water in the environment, including rainfall, ponds, rivers, or anywhere that water collects and can be a source for drinking. Most animals depend on drinking water from the environment during variable (usually regular) times during their lives. The amounts required depend on the humidity of the environment, how

an animal behaves within its environment, and the efficacy of traits that conserve water in environments or circumstances where conditions are dehydrating. In extreme cases, animals with exceptional specializations for conserving water might get by on dietary and metabolic water and not require sources for drinking. Examples are certain desert rodents that produce a highly concentrated urine, minimize evaporative water losses, and acquire sufficient water by eating and metabolizing seeds that are stored in burrows where they absorb very small but critical amounts of water (Nagy and Gruchacz 1994).

Many animals acquire considerable water in the food they eat, especially herbivores that graze or browse on vegetation. Depending on whether environmental conditions are relatively humid or dry, animals show selective behaviors with respect to the nature and content of water in the vegetation they consume. Rodents that do not have direct access to water may consume succulent plants and their fruits. Deer and other ungulates are well-studied examples of animals that change selective feeding behavior that matches the water content of foliage with the need for water (Western 1975). Larger animals that cannot satisfy their need for water from dietary items might depend on sources of free water such as water holes that are visited within broad ranges of movement, while birds can fly long distances to find sources of water. Amphibians, alligators, and other animals also migrate variable distances at times of drought when local water sources dry out. Thus, survival of animals faced with water shortages depends on behavioral choices – movements and other activities.

The reliance of marine snakes on free water is an interesting example of osmoregulation in the context of the evolutionary transition from terrestrial to marine environments (Dunson and Mazzotti 1989). The rates of salt secretion from salt glands vary among species of sea snakes and tend to be higher in those species that occupy waters of greater salinity and have greater oceanic ranges (Brischoux et al. 2012). However, contrary to earlier views, marine file snakes, sea kraits, and sea snakes depend on environmental sources of fresh water to remain in water balance (Lillywhite

et al. 2008, 2014a, b). Thus, the distribution and abundance of sea kraits (*Laticauda* spp.) correlates with precipitation and the spatial distribution of coastal springs or estuaries (Lillywhite et al. 2008). With respect to sea snakes that are entirely pelagic, or inhabit reefs that are some distances from land, the only (or principal) access to fresh water is drinking from fresh- or brackish water lenses that form temporarily on the ocean surface during intense rainfall. Observations and other evidence suggests that sea snakes can sense the quality of water, largely by tongue-flicking, and drinking behaviors are guided by sensory inputs to the snake's central nervous system (Lillywhite et al. 2014a).

### Adaptations for Conservation of Water

Animals that have invaded or evolved in comparatively arid habitats illustrate adaptations of structural, physiological, and behavioral features that act to conserve water. One of the principal strategies for dealing with scarcity of water is the behavioral avoidance of conditions that exacerbate water loss. Hence, many desert animals seek out cooler and moister microenvironments. Examples include small mammals and reptiles that dig or occupy burrows in soil, sleeping away the day in deep crevices, holes, or jumbles of rocks at the bases of cliffs, and restricting above-ground or open-habitat behaviors to nocturnal hours when temperatures are cooler and the air is more humid. Also, many animals living in extreme environments avoid seasonal conditions that limit energy or water by hibernating (winter) or estivating (summer) in seclusion from the harsh conditions of the environment at or above the ground. Moreover, amphibians that live in deserts will remain dormant below ground for much of the year (or longer in drought conditions), to emerge for feeding and breeding only during rare or seasonal periods of rainfall. Generally, amphibians are very sensitive to losses of water, mostly through skin that is highly permeable and evaporates body water at high rates. With the exception discussed below, frogs, toads and salamanders simply cannot withstand exposure to arid

conditions that are tolerated by lizards, tortoises, and mammals and birds having much less permeable integument (McNab 2002).

Avoidance of higher temperatures is important because mammals, for example, must eliminate excess heat by evaporation of water in sweating or panting (McNab 2002). Avoidance of heat gains from hot environments saves valuable water that would otherwise be expended for sake of thermoregulation. Birds can usually avoid heat gains by flying to cooler locations in desert canyons or shaded areas, sometimes with springs of fresh water. If birds become heated to the point of being hyperthermic, like mammals they increase evaporative cooling, but not by panting. Instead, they “flutter” the throat and bring air in and out across the gular membranes in the mouth and throat. Some species – for example, vultures – urinate on their “naked” legs. The urine evaporates to cool the legs and remove excess body heat. Some desert mammals, including camels, tolerate mild hyperthermia for short periods, conserving water that would otherwise be expended in evaporative cooling to regulate the body temperature at a lower set point.

As already noted, excretion of urine necessarily eliminates water, so modifications of kidney tubules to excrete a concentrated urine conserves water relative to the solutes and metabolic wastes that need to be eliminated from the body. Birds and squamate reptiles cannot produce a concentrated urine like that of mammals, but elimination of nitrogenous wastes from metabolism of protein is in the form of uric acid (or urates) instead of urea or ammonia. Uric acid can precipitate from solution in the hindgut or cloaca, and is thus excreted with minimal loss of water compared with urea or ammonia that remain in solution and require more water for elimination. Thus, modifications of kidney function to produce concentrated urine, elimination of uric acid from metabolism of protein, and concentrated solutions from salt glands are all adaptations of structure and function to minimize losses of water in the excretion of metabolic wastes.

Other important adaptations conserve water by reducing water losses in evaporation incurred by ventilating the lung (respiratory losses) or from

skin or body surfaces (Fig. 1). Some desert animals have relatively low requirements for energy (e.g., Nagy et al. 1993). Lower rates of metabolism reduce respiratory water losses attributable to ventilation of the lung. Low energy requirements also reduce foraging time and thus conserve water otherwise expended during these activities. Reduced activity, including dormancy and seclusion, generally reduces water loss, and reduced water flux generally correlates with lower field metabolic rates.

A very important route for water exchange involves the skin. The skin of vertebrates evolved to meet the needs for mechanical protection, sensing the environment, and regulating exchanges of materials and energy. The skin is a complex structure that resists water loss and physical abrasion while also allowing for changes in movement and shape. Amphibian skin has only one or two outermost layers of keratin and is generally very permeable to water. Hence, many species require mesic environments or places where they can associate with water to avoid or replenish losses. The majority of other terrestrial vertebrates have less permeable skin in which the outer layers of keratin (stratum corneum of the epidermis) are sandwiched between layers of lipids that protect the internal cellular environment from the dehydrating effects of surrounding air (Lillywhite 2006). The outer layers of keratin and lipids form what is termed the “permeability barrier,” and the respective structure and biochemistry of this barrier determines the ease with which water can penetrate or move across the skin. Generally, birds, mammals, and reptiles living in arid environments have a more effective lipid barrier and less permeable skin than do species living in mesic environments. Permeability barriers have evolved independently many times in the various groups of terrestrial vertebrates, and studies demonstrate that some species have “plastic barriers” that can (to some extent) be modulated to match efficacy with changes in the severity of environmental conditions (Denda et al. 1998).

Amphibians are exceptional in having very few keratin layers in their skin; hence their permeability barriers are relatively ineffectual or

absent. Yet, there are many species of amphibians that live in arid environments, generally by avoiding the harshest conditions by seclusion. Several species of tree frogs, however, representing different taxa in the Old and New World, remain above-ground and may even rest on tree branches in direct sunlight on hot days. These frogs secrete mixtures of lipids from specialized cutaneous glands and then wipe themselves to spread these secretions over the entire body surface. This happens just before activity ceases and the frogs adopt a resting posture. The wiping behavior is stereotyped and functions to “wax” the skin surfaces evenly and completely. Thus, in place of a permeability barrier within the skin, these frogs secrete the barrier onto the outer surfaces of the skin. When the frogs move again, the integrity of the outer lipid film is disrupted, so the barrier must be periodically renewed.

Finally, some burrowing species of desert frogs shed multiple layers of epidermis that remain in place when these animals are secluded and dormant beneath soil (e.g., in deserts). The multiple layers of shed epidermis coalesce and collectively form what is called a “cocoon.” Such cocoons greatly increase the resistance to water loss by virtue of morphology that is somewhat similar to the multiple layers of keratin and lipids in the epidermis of mammals, birds, and reptiles. Some amount of lipids occur between the multiple layers of shed skin, but their role in the function of the cocoon has not been definitively worked out.

## The Importance of Behavior

Many aspects of behavior influence the savings of water. These include movements, thermoregulation, postural adjustments, selection of humidity or hydric conditions in microenvironments, patterns of breathing, bodily contact with conspecific individuals, responses to weather, timing of migration, dispersal, or burrowing, foraging strategies, and many other examples I will not list here. Insights to the importance of behavior to water balance in extreme or changing environments is important to understanding the survival and

resilience of organisms and their communities, and predicting the range of responses to future climatic changes. Research that integrates studies in physiology, genetics, morphology, and natural history in contexts related to water balance will greatly help us understand the complexity of underpinnings to behavior. In turn, behavioral activities of animals influence the adaptations of morphology and physiology related to water balance.

## Definition

Waterfowl are birds that are members of the order Anseriformes, which includes three families: Anseranatidae (magpie geese), Anhimidae (screamers), and Anatidae (ducks, geese, and swans).

## Introduction

Waterfowl are birds within the order Anseriformes, which is made up of three families: Anseranatidae

(magpie geese), Anhimidae (screamers), and Anatidae (ducks, geese, and swans). Waterfowl are adapted to life in or near the water, and their anatomy reflects their aquatic lifestyle. The three families of waterfowl share many of these characteristics and adaptations but also have several unique traits that distinguish them not only from each other but also from all birds. Although all waterfowl live on or near a body of water, this can vary greatly from mountain streams to coastal shores to tundra lakes, and they utilize these bodies of water in different ways. Waterfowl are ubiquitous and can be found on every continent except Antarctica, and most waterfowl migrate to some degree. Gregariousness, or a high degree of sociality, and monogamy are hallmarks of most waterfowl life, although like most other aspects of waterfowl life, there is a great deal of variation. Waterfowl tend to lay large clutches of large eggs and hatch precocial chicks that require very little parental care. Many traits that characterize waterfowl, including their global distribution, wide array of diets, and precocial chicks, likely paved the path for their domestication by humans. These domestication and interweaving of waterfowl life with human life have important implications both for waterfowl and for humans.

## Taxonomy

Waterfowl are generally considered to be birds within the order Anseriformes. Anseriformes (“waterfowl”) and Galliformes (“game birds”) make up the superorder Galloanserae (“fowl”). These two orders split from each other approximately 54 million years ago (Prum et al. 2015). Within the order Anseriformes, there are three families: Anseranatidae (magpie geese), Anhimidae (screamers), and Anatidae (ducks, geese, and swans). The specific relationship between the families, subfamilies, and tribes that make up Anseriformes remains a contested subject, with much disagreement within the scientific community. For the purposes of this entry, the taxonomic relationships described by del Hoyo et al. (2019) will be used.

Anseranatidae is a family consisting of just one species, the magpie goose, *Anseranas semi-palmata*. Although this species was historically classified as a member of the family Anatidae, the most recent evidence places it instead in its own family (Carboneras and Kirwan 2019b). Magpie geese are considered to be the most primitive, or ancestral, branch of the Anseriformes order.

Anhimidae is the family to which screamers belong. The family consists of two genera and three species. This family is usually classified as being more closely related to Anseranatids than to Anatids (Carboneras 2019b).

The family Anatidae includes ducks, geese, and swans and contains the vast majority of waterfowl species – 165 of the 169 species within the order (Carboneras 2019a). Within this family, there are four subfamilies: Anserinae (swans and “true” geese), Oxyurinae (ducks more closely related to Anserinae), Dendrocygninae (whistling ducks and white-backed ducks), and Anatinae (sea ducks, diving ducks, shelducks and sheldgeese, perching ducks, and dabbling ducks). Anserinae and Anatinae together are sometimes described as “wildfowl” (Carboneras 2019a).

## Anatomy, Morphology, and Adaptations

In general, all waterfowl are adapted to life in or near the water, and they share many anatomical features that allow them to thrive in this aquatic lifestyle. Although there is a great range in body size from the large trumpeter swan to the small African pygmy goose, Carboneras (2019a) describes several general trends among waterfowl that hold true across the order. Firstly, most waterfowl tend to have longer, flatter bodies which improve buoyancy on the water and shorter tail feathers. The most aquatic species tend to have legs situated more caudally, or toward the tail, which increases buoyancy but makes walking on land more awkward and gives them their distinct waddle. They also have characteristic webbing between their toes allowing them to swim more quickly and efficiently. Furthermore, most

waterfowl have well-developed uropygial or preen glands, which are oil-secreting glands located just above the tail, that birds use to coat their feathers, making them better able to repel water. Many waterfowl also have salt glands situated above their eyes that filter out salt from their blood and secrete it out of their bodies. These glands vary in their prominence, depending on how brackish the water is in individual species' habitats. Finally, they also have long, flattish bills with lamellae or comb-like projections from their beak used to filter out food from the water. Different species have lamellae of different sizes and densities, based on the food that they primarily eat.

Waterfowl also share anatomical traits beyond life on the water. Unlike most other birds, male waterfowl have sex organs that can be everted to become external and roughly comparable to mammalian penises (Scott 2010). Most other bird orders copulate by direct cloacal contact which does not require any sort of penetration. Waterfowl males, however, have retained an external penis that enters the female's oviduct (Herrera et al. 2013). Relatedly, female waterfowl tend to have much more complicated oviducts than other bird orders (Brennan et al. 2009). There isn't a consensus explanation for these striking anatomical differences between waterfowl and other bird orders, but Herrera et al. (2013) suggest that sexual selection plays an important role. Furthermore, Brennan et al. (2009) argue that complex male and female waterfowl anatomy coevolved as an "arms race" of sorts to determine the success of forced copulation.

Although the different families of waterfowl share many of the same characteristics, there are several important differences between families. For example, most ducks, geese, and swans (i.e., members of the family Anatidae or "anatids") molt all of their feathers at once, rendering them completely flightless during short periods of time as their feathers regrow (Carboneras 2019a). Screamers and magpie geese, however, molt their feathers more gradually and therefore retain their ability to fly year round (Carboneras 2019a; Carboneras and Kirwan 2019b).

Magpie geese (i.e., the sole species of Anseranatidae) also exhibit some unique anatomical traits that separate them from other waterfowl. Magpie geese, especially males, have an extremely long, folded trachea that is thought to play a role in vocalizations related to mating (Whitehead 1998). They also feature a prominent head protuberance that is significantly larger in males and in older birds (Whitehead 1998). Both of these sexually dimorphic features likely evolved due to sexual selection pressures exerted by the unusual polygamous mating system employed by the species that is discussed later on in this entry (Whitehead 1998).

Screamers (i.e., the three species that make up the family Anhimidae) also have several characteristics that make them unique from other waterfowl. Although screamers are capable of swimming, they are unlike other waterfowl in that they spend most of their time walking in the marshy vegetation around bodies of water as opposed to swimming in the water itself (Carboneras 2019b). Their toes, therefore, are less webbed than those of other waterfowl families and are longer and more spread out, allowing them to traverse marshy areas (Carboneras 2019b). Screamers also have bony spurs on the carpal (wrist) bones of their wings, and as noted by Carboneras (2019b), these spurs are likely used for territorial defense.

Screamers also have several traits that distinguish them from birds in general, not just waterfowl. For example, most birds grow feathers in distinct tracts or lines of feather follicles (Scott 2010). Screamers, however, lack these feather tracts and grow feathers evenly throughout their bodies (Carboneras 2019b). Furthermore, although the majority of birds have pneumatic – air-filled or "hollow" – bones, screamers have some of the most highly pneumatic bones of any bird species, which may allow them to fly at higher altitudes (O'Connor 2004; Picasso et al. 2014). Picasso et al. (2014) also suggest that another unique feature of screamers may aid in high-altitude flight: subcutaneous diverticula or air sacs that sit just below the skin and crackle when compressed. Finally, screamers lack uncinate processes which are bony "hooks" that

extend from the ribs of all other bird species (Tickle et al. 2007). Tickle et al. (2007) suggest that these hooks might increase the efficacy of respiration, and note that their length and prominence are somewhat associated with different forms of locomotion in birds. Thus far, however, their absence in screamers is unexplained.

## Feeding and Diet

Waterfowl employ several different methods of feeding including grazing, filter feeding/dabbling, and diving. All waterfowl with the potential exception of screamers employ filter feeding or dabbling as a feeding method (Carboneras 2019a, b). The basic process of dabbling involves sucking water through the bill and then pushing it back out through the lamellae that line the beak in order to trap plankton, algae, etc. which is then pushed back into the bird's throat with its tongue (Hughes and Green 2005). Although most waterfowl utilize dabbling as a feeding method, some rely on it more heavily than others. As noted by Hughes and Green (2005), the number of lamellae a species has on its bill corresponds to the individual species' diet. For example, a diving duck that tends to swallow whole fish or larger mollusks would be expected to have fewer lamellae than a dabbling duck that primarily eats plankton. The size and shape of waterfowl's bills also correspond to the type of food that an individual eats (Hughes and Green 2005). For example, a northern shoveler's (*Spatula clypeata*) wide, flat bill is indicative of the smaller plankton it eats, whereas a long-tailed duck's (*Clangula hyemalis*) shorter, narrower bill suggests it eats larger crustaceans and fish (Carboneras and Kirwan 2019a, c).

In addition to employing several different feeding methods, there is also a wide range of diets across the order. Screamers are herbivores, primarily eating aquatic plant matter. They may occasionally eat insects, especially when raising chicks (Carboneras 2019b). Magpie geese are also primarily herbivores, focusing on grasses, seeds, and tubers. They will use their feet to bend tall grasses down, exposing the seeds and roots underneath for them to eat (Johnsgard 2010). Magpie geese dig through muddy areas to find plant

matter as well as filtering mud through their beaks to consume smaller pieces of plant matter (Carboneras and Kirwan 2019b).

Among anatids, "true" geese and swans (members of the subfamily Anserinae) tend to be herbivorous throughout their lifetimes, whereas ducks vary much more in their diets (Carboneras 2019a). There is a wide range of diet patterns within ducks, ranging from strictly herbivorous to strictly carnivorous. A pattern noted by Carboneras (2019a) is that duck species whose habitats are in estuaries or oceans (i.e., further from land) tend to be more carnivorous while more terrestrial ducks tend to be more herbivorous. In addition to environmental factors, seasonality affects waterfowl diets, as well. One individual bird of any given waterfowl species may shift its diet between the breeding and non-breeding seasons. For example, McLandress and Raveling (1981) noted that Canada geese (*Branta canadensis*) shifted their primary diets from corn during the winter to a much higher diversity of items, especially those with protein, in preparation for migration and eventual breeding.

## Distribution and Habitat

Waterfowl can be found on every continent except Antarctica (Carboneras 2019a, b; Carboneras and Kirwan 2019b). Individual subfamilies are rarely found in only one geographic region of the world. Even a single species, such as the white-faced whistling duck (*Dendrocygna viduata*), can be found on multiple continents (Carboneras and Kirwan 2019d). Screamers can be found throughout most of the continent of South America (Carboneras 2019b). Magpie geese live along the northern coast of Australia and the southern coast of New Guinea (Carboneras and Kirwan 2019b).

In addition to their wide distribution, waterfowl are found in many different types of aquatic habitats, from oceans to ponds to creeks. As you might expect, diving ducks usually prefer deeper water than do dabbling ducks (Carboneras 2019a). Geese tend to choose marshier areas adjacent to grasslands and meadows (Carboneras 2019a). Two species, torrent ducks (*Merganetta armata*) and blue ducks (*Hymenolaimus*

*malacorhynchos*), even prefer rivers and streams with rapid currents (Carboneras 2019a).

Different species also spend varying amounts of time in close proximity to water. For example, king eiders (*Somateria spectabilis*) spend almost the entirety of the non-breeding season on the ocean, and even when they do breed, they nest close to the water (Carboneras 2019a). On the other hand, many geese spend a lot of time at great distances from water (Carboneras 2019a). Furthermore, different waterfowl species change their habitat preferences and habits seasonally. Harlequin ducks (*Histrionicus histrionicus*) spend the breeding season near fast-moving streams in the mountains but spend the non-breeding season in coastal marine areas (Carboneras 2019a).

## Migration

Many waterfowl species migrate to some degree or another, but like most other aspects of waterfowl life, there is a lot of variation. There's variation within families, species, and even populations. In a pattern noted in other bird orders, waterfowl species that live closer to the tropics tend to be less migratory than those species that live closer to the poles (Carboneras 2019a, b). For instance, although screamers as a family are not considered migrants and species and populations closer to the tropics tend to stay close to their breeding grounds year round, those further from the tropics do travel significant distances (Carboneras 2019b).

There are two general migration patterns: "organized" migration where a population of a species moves from a roughly defined point A to a roughly defined point B on a regular time table (e.g., geese) and necessity-based migration in which a population of a species moves away from an area only at the point at which it becomes necessary based on weather or environmental conditions (e.g., mergansers) (Carboneras 2019a). An example of this latter pattern is a "drought migration" which occurs when a body of water on which a bird or species is reliant dries up, forcing the bird to find another suitable location (Carboneras 2019a). Birds that exemplify this

latter pattern tend to travel shorter distances, only moving as far as they have to, while birds that migrate in a more traditional sense can travel very long distances.

Long-distance migration is inherently risky, and according to Scott (2010), only about 60% of waterfowl that migrate south from North America return to breed the next year. One of the largest risks of long-distance migration is energy depletion. In preparation for migration, migrating waterfowl will enter a period of hyperphagia or overeating. A 1981 analysis by McLandress and Raveling found that the body weight of Canada geese increased to 26–36% during this period of hyperphagia. In addition to storing extra energy, migrating waterfowl also try to conserve energy however possible, and the characteristic "v" formation of migrating geese is likely an energy-saving technique (Weimerskirch et al. 2001).

## Sociality and Flocking

In general, gregariousness, or a high degree of sociality, is a hallmark of most waterfowl life. Most species of waterfowl form flocks for at least part of the year, although swans, geese, and perennially monogamous ducks (see "Mating Systems" below) tend to be more solitary than the rest of the waterfowl order (Carboneras 2019a). Large flocks provide several advantages, including predator protection. This is especially important for waterfowl that molt all of their feathers at once and experience periods of total flightlessness (Carboneras 2019a). They are very vulnerable to predation during these times so flocking is an important defense mechanism. Therefore, maintaining social cohesion is an important part of waterfowl life. Waterfowl have several methods of maintaining social cohesion such as species-specific wing specula (the brightly colored or iridescent patch of secondary feathers on their wings) and contact calls (Carboneras 2019a). Beyond specific species, waterfowl also often form mixed-species flocks, especially during winter when predator protection trumps breeding considerations (Carboneras 2019a).

Although gregariousness is common in waterfowl, there is variation not only between species

but also within species at different times of the year. In areas where seasons are less defined (i.e., more tropical areas), breeding can occur year round (Carboneras 2019a). In more temperate areas, however, there are stark differences in weather and temperature between seasons, and these differences necessitate more strictly defined breeding seasons (Carboneras 2019a). Without the option to breed outside of a certain window, species living in more temperate areas often exhibit vastly different social organizations at different times of year. Southern screamers, for example, are highly gregarious during the non-breeding season and can be found in flocks consisting of a few to potentially thousands of birds. During the breeding season, however, they tend to spread apart, form pairs, and become defensive of a territory.

## Mating Systems

The vast majority of waterfowl species employ a monogamous mating system in which two birds form a pair that stays together for the duration of a breeding season (Bowler 2005; Carboneras 2019a). Most ducks, specifically those in the subfamily Anatinae, form pair bonds during the breeding season but do not tend to maintain these bonds year after year (Carboneras 2019a). Instead, they tend to pair with a different mate in each subsequent breeding season in a system defined as annual monogamy (Bowler 2005). Some suggest that annual monogamy may be a method for maintaining group cohesion (Carboneras 2019a). Eiders, sea ducks, and river specialists such as blue ducks and torrent ducks, however, are exceptions to this rule and tend to pair with the same individual every year (Carboneras 2019a). In a similar vein, swans and geese tend to form permanent pair bonds that last over a bird's lifetime. This system is referred to as perennial monogamy (Bowler 2005).

Polygamous mating systems in which one male breeds with multiple females within a single breeding season is rare in waterfowl but is practiced by American (*Sarkidiornis sylvicola*) and African (*Sarkidiornis melanotos*) comb ducks,

Maccoa ducks (*Oxyura maccoa*), and magpie geese, albeit in different ways. Maccoa duck males defend a territory that is large enough for several females, but the males do not form strong pair bonds with any of the females in their territory (Bowler 2005; Carboneras et al. 2019). Magpie geese males, on the other hand, permanently bond with two females, and all three adults incubate and raise chicks together (Carboneras and Kirwan 2019b).

## Courtship, Nesting, and Incubation

The onset of breeding season usually occurs in the spring, just after spring migration, excepting birds in more tropical areas and/or those that don't migrate. Courtship rituals are closely tied to the mating system a particular species exhibits, and species that practice annual monogamy tend to have much more elaborate courtship displays than do species that practice perennial monogamy (Carboneras 2019a).

Waterfowl practicing annual monogamy typically pair up at the end of the non-breeding season when they are in their wintering grounds (Carboneras 2019a). Female waterfowl exhibit a high degree of natal philopatry, or the tendency to return to the site where they hatched, so once paired, males tend to follow their mate's migration path from the wintering ground to the female's natal site (Anderson et al. 1992).

Most waterfowl nests are simple scrapes (depressions in the ground) made in close proximity to water (Carboneras 2019a). The nests are usually built with a few sticks, grasses, and a liner of down feathers. There are, however, some cavity-nesting waterfowl, such as spotted whistling ducks (*Dendrocygna guttata*), and cliff nesters, such as barnacle geese (*Branta leucopsis*) (Carboneras 2019a). Furthermore, some species of waterfowl build their nests in colonies, meaning the nests are in very close proximity to each other, while others build their nests in a defined territory that they defend to varying degrees (Carboneras 2019a).

Most waterfowl species lay large clutches of relatively large eggs (Carboneras 2019a). Large

clutches ensure that some chicks survive despite a high mortality rate, and large eggs are better insulated in the wetter environment frequented by most waterfowl species. Both of these strategies, however, require a large caloric investment by the female, so each species balances clutch size and egg size in a slightly different way (Christians 2000).

Males usually do not incubate although some species with perennial monogamy or polygamy break this trend. For example, some male whistling ducks will incubate when the female is off the nest to forage, but they do not split the job evenly with females (Carboneras 2019a). Polygamous magpie geese exhibit a very unusual system in which both females paired with a single male lay their eggs in one nest and all three adults incubate eggs (Carboneras and Kirwan 2019b). For all waterfowl, incubation starts after the last egg is laid to help ensure synchronous hatching (Carboneras 2019a). This is important because, as will be discussed later in this entry, waterfowl are known for having highly nidifugous or precocial chicks (Carboneras 2019a). This means that chicks are relatively independent upon hatching and are able to walk and find food for themselves almost immediately. Synchronous hatching is important for large clutches of precocial chicks because the window of time between a chick hatching and leaving the nest is small, and if all chicks are not in the same location, only some of them can be protected at any given time.

One interesting pattern noted in many waterfowl species is conspecific brood parasitism or CBP. CBP occurs when a female lays eggs in the nest of a different female of the same species (Pöysä et al. 2014). These eggs are raised by the owner of the nest and not the biological parent (or “parasite”), meaning that the parasite’s genes are passed on, but the parasite avoids the costs incurred by parental investment. CBP appears to be more prevalent in waterfowl than in any other order of bird with almost 50% of species showing evidence of using CBP as a strategy (although Yom-Tov (2001) notes that this percentage could actually be considerably higher). This prevalence may be explained by a few aforementioned characteristics of waterfowl reproduction: colonial

nesting, precocial chicks, and large, synchronously hatching clutches. Birds that nest in large colonies often face nest site availability as a limiting factor. If a parasite is unable to secure a nest site, she may use CBP as a way to raise chicks without needing a territory of her own. Furthermore, precocial chicks require less parental investment than do altricial (less developed) chicks, making it more possible for foster parents to accommodate a larger brood. Finally, because waterfowl tend to lay large clutches that are not incubated (i.e., protected) until the final egg is laid, the parasite has ample opportunity to access another female’s nest (Yom-Tov 2001).

## Chick Rearing and Parental Investment

As noted earlier, waterfowl species are known for having highly precocial chicks. Precocial chicks are much less reliant on their parents, and therefore much less parental investment is required. As a general rule, male waterfowl (especially males of annually monogamous species) do not provide any parental care, although perennially monogamous species and magpie geese are the exceptions to this rule (Carboneras 2019a). Further, parents usually do not feed chicks but rather “show” them where food is. This is usually a relatively passive process, but some birds like magpie geese take a slightly more active role by holding food in their mouths, sometimes actively feeding it to them (Carboneras and Kirwan 2019b). Some waterfowl species, especially those that nest in colonies, will form crèches (“nurseries”) in which young are collectively cared for by the larger flock (Bowler 2005). This is an important method for predator protection at a time when chicks are especially vulnerable. Most waterfowl chicks become independent after just a few months and disperse from their parents completely and form breeding pairs of their own after just 1 year (Carboneras 2019a). Geese chicks are unusual in that they may stay with their parents and migrate along with them for the first couple years of life, potentially helping them protect the next clutch of chicks their parents lay (Carboneras 2019a).

## Relationship with Humans and Domestication

Waterfowl have a unique relationship with humans due to the large number of domesticated waterfowl breeds. Waterfowl have been used by humans for food, feathers/down, quills, and diversion and even as guards in the case of geese (Carboneras 2019a). Many different waterfowl species, namely, anatids, were likely domesticated soon after the emergence of agricultural societies (Carboneras 2019a). Larson and Burger (2013) describe the pathway that waterfowl, namely, ducks, likely took toward domestication. Per Larson and Burger (2013), waterfowl likely followed a commensal pathway in which they first began to exploit environments created by humans (i.e., feeding off of human waste products or crops), and then humans increasingly took a more active role in managing populations of the birds. Waterfowl exhibit several traits that allow them to be more easily domesticated, such as their large brood size, precocial chicks requiring minimal care, and wide variety of diet (Zeder 2012). Furthermore, as waterfowl are found all over the globe, many different human societies were exposed to waterfowl species.

## Conservation

Likely due to their adaptability and large dispersal over the globe, waterfowl as an order is not particularly threatened. Seventy four percent of the species in the family Anatidae are listed as being of least concern by the International Union for Conservation of Nature (IUCN) Red List (Carboneras 2019a). Only 14 species, or 9%, or species within Anatidae are endangered or critically endangered (Carboneras 2019a). The common threats to those waterfowl species that are endangered include habitat loss and human interference. A less obvious potential threat to waterfowl is hybridization (Scott 2010). Waterfowl as an order have the highest known potential to hybridize among birds (Ottenburghs et al. 2016). An incredible 77% of waterfowl species is known

to have hybridized at some point, whether in the wild or captivity (Ottenburghs et al. 2016).

The ease of hybridization between different waterfowl species combined with human interference poses a serious threat. A clear example of this is the threat of genetic swamping – a replacement of a species' genotype by a hybrid genotype – of the endangered white-headed duck (*Oxyura leucocephala*) by the ruddy duck (*Oxyura jamaicensis*) (Scott 2010). As Scott (2010) describes, in the mid-twentieth century, a small population of ruddy ducks were accidentally released from a captive collection in Britain. This small population went on to breed with white-headed duck populations across Europe, creating not only hybrids but also fertile hybrids that lead to second-generation hybridization (Scott 2010). Conservation laws and programs aimed at controlling the population of ruddy duck are now in place, but white-headed ducks remain endangered (Scott 2010).

Human interference can benefit species, as well, through the use of captive reintroduction programs. In 1949, the nene goose (*Branta sandvicensis*) was endangered, with only 30 individuals known in the wild (Black 1995). A conservation program was begun by the Wildfowl & Wetlands Trust, and between 1960 and 1993, over 2000 captive-bred individuals were released into sanctuaries in the wild (Black 1995). Today, although the nene goose population is still vulnerable, it is no longer critically endangered, and it is increasing (BirdLife International 2017). This exemplifies the potential to change the course of endangered waterfowl species and highlights the importance of concerted conservation efforts as human populations continue to grow and encroach on the habitats of waterfowl.

## Conclusion

Waterfowl is a large and diverse order, but its members are connected through several unique characteristics. The three families of waterfowl share many attributes but also have several unique traits that distinguish them not only from each other but also from all birds. The domestication

of many species of waterfowl and their relationship with humans has impacts on their lives as well as our own.

## Definition

It is the period during which an infant is made to replace breast or formula milk completely with other foods and drinks.

## Introduction

Breast milk is known to be the best for the baby as it provides all the required nutrition (Michaelson et al. 2000) as well as the antibodies that help improve the immune system. Breastfeeding can be continued as long as the baby and mother are comfortable. In certain incidences that include low or no breast milk production or inability of mother to feed the baby due to illness, physical challenges, going back to work or other conditions, formula milk especially designed as per the nutritional requirements of the baby may be introduced. According to the World Health Organization (2001), it is recommended that a child must be exclusively on breast milk for a period of 6 months. In any case, after 6 months breast milk (or formula) alone is not sufficient for the baby as there is a requirement of more calories and nutrients than what breast milk (or formula) can supply. Insufficient vitamin D may constitute a problem if the baby is not properly exposed to sunlight (Dewey 2001) and zinc may also reach to marginal levels in infants from 4 to 5 months of age onwards (Jalla et al. 2002). Some fully breastfed infants may occasionally be deficient of iron, and vitamins A, B12, and riboflavin (WHO 1998). It is necessary to introduce complementary foods in the baby's diet in addition to the breast milk to fulfill the

changing nutritional requirements. These are called complementary foods because they do not replace breast milk (or formula) rather they “complement” or “add” to it and hence enrich the baby’s diet. Ideally, the intake of complementary foods should be gradual with a variety of tastes preferably based on the foods eaten by the family (Brown and Lee 2013). This process of introduction of solid foods and gradually replacing all the breast (or formula) milk is called as weaning. Therefore, weaning is not an event rather a gradual process that starts with the first introduction of solid food and ends with the last intake of breast (or formula) milk.

Breastfeeding is not only a source of nourishment but it also provides comfort, affection, and security to the baby. While starting the process of weaning, it should be kept in mind that in addition to fulfilling the baby’s enhanced nutritional need, his emotional comfort should also be taken care of by providing extra love and attention. Weaning may be classified on the basis of duration of the process (Gradual or Sudden) and on who drives the process (Baby-led or Mother-led).

### Gradual Weaning

It is the process in which the breastfeeding sessions are slowly eliminated over a long period of time until the baby stops nursing. It offers many emotional and physical benefits to both mother and the baby. It is more readily accepted by the baby. Physically it allows the milk supply to decrease at a natural rate as the hormones producing milk decrease gradually. This lowers the risk of painful breast engorgement, plugged milk ducts, and breast infection (mastitis).

### Sudden Weaning

An abrupt or sudden elimination of breastfeeding may be highly challenging to both mother and baby. Breastfeeding builds a bond between baby and mother. For an infant, it is difficult to understand why breast milk is suddenly not available that may make him demanding, cranky, and difficult to soothe down. The mother is also at risk of

facing physical challenges like breast engorgement, clogged milk ducts, and mastitis.

### Baby-Led Weaning

Baby-led weaning, also called child-led or natural weaning, happens when the baby starts accepting more of solid foods in addition to on-demand breastfeeding. This method is not only natural but also safe and easy. It significantly helps in improving a baby’s chewing skills, eating pattern, hand-eye coordination, manual agility and leads to a healthier body weight (Cameron et al. 2012). A constant eye should be kept on the baby cues like hunger and satiety, pushing away the breast, interest in the food eaten by the family and many others. When allowed to self-wean, babies wean between 2 and 4 years of age.

### Mother-Led Weaning

Mother-led weaning is also sometimes called planned or parent-led weaning. The mother (or parent) decides the type and quantity of food to be introduced to the baby, when to offer breast and when to offer bottle, and how to progress with the process. It is possible that the child may show a lot of protest during the weaning process as he is truly not ready for it. It is important to understand that the child is emotionally bonded to the mother by breast feed and therefore it is essential to be patient, flexible, and respectful to child’s needs during the weaning process.

### Conclusion

Breast milk is best for the baby up to 6 months of age; however, after this age it might not fulfill all the nutritional requirement of the baby. Therefore, complementary foods that enhance the nutrient value should be added to baby’s diet. A sudden elimination of breastfeeding may have emotional and physical consequences on both the mother and baby; therefore, it is recommended that breast milk should be replaced gradually.

## Whole Genome Amplification

Maheswari Kulandhasamy  
Jawaharlal Institute of Postgraduate Medical Education and Research (JIPMER), Karaikal, Puducherry, India  
Department of Biochemistry, Maulana Azad Medical College, New Delhi, India

## Introduction

DNA samples obtained from different sources, namely, single cell (Zhang et al. 1992), tissue biopsies, culture cells, and forensic and tumor samples, may be limited in quantity for various analysis. Amplification of DNA fragments for further experiments can be obtained through different types of polymerase chain reaction (PCR). These techniques have some challenges such as limited DNA yield, and only a particular region of chromosome can be studied. To study the whole genome, the demands cannot be met by using these techniques. These limitations paved a way to develop a new technique to overcome these problems and get a good yield of DNA.

## What Is WGA?

Whole genome amplification (WGA) technique involves modification of conventional PCR method through which the whole genome gets covered to give a good amplification efficiency. Micrograms of DNA can be synthesized from ng or lesser amounts.

PCR-based WGA includes:

1. LA-PCR (linker adapter/ligation-anchored PCR)
2. IRS PCR (interspersed repetitive sequence PCR)
3. PEP PCR (primer extension preamplification PCR) (Zhang et al., 1992)
4. DOP PCR (degenerate oligonucleotide primed PCR) (Telenius et al. 1992).
5. D-DOP PCR (displacement degenerate oligonucleotide primed PCR)

### LA PCR

Adaptors will be ligated to embedded PCR primer sites and it will be amplified.

### IRS PCR

Primers will be designed to known repetitive sequences in the genomic DNA, and they will bind and amplify the DNA.

### PEP PCR

It utilizes random 15-mer PCR primers and low annealing temperature during PCR.

### DOP PCR

It utilizes semi-degenerate oligonucleotides (i.e., CGACTCGAGNNNNNATGTGG) and an increasing annealing temperature.

Each of this method varies in their primer design. These were the first-generation WGA techniques. The use of *Taq* DNA polymerase in PCR-based techniques limits the fragment lengths less than 3 kb with errors in the sequence. Error rates are high, and only 1–2 kb length product can be obtained in most of these multistep techniques. The use of *Taq* polymerase in PCR-based techniques introduces a number of errors in the amplified sequence. Fidelity properties of PCR

enzymes determine the error rate. The higher the fidelity, the lower the error rates during amplification.

Error frequencies occur in the range of  $10^{-4}$  to  $10^{-5}$  mutations/bp amplified. Limitations of these techniques include incomplete genome coverage and amplification bias.

Most WGA techniques involve some variation in accuracy compared to the original unamplified material. The various protocols introduce different rates of artifact formation, allelic dropout, and loss of sequence coverage over the genome. So it is important to choose a technique which minimize dropout and do preferential amplification, increase genome coverage, or maximize accurate base replication.

Non-PCR-based WGA methods include:

1. MDA (multiple displacement amplification)
2. SPIA (single primer isothermal amplification)
3. MALBAC (multiple annealing and looping-based amplification cycles)

### MDA

This involves the binding of random hexamers to denatured DNA followed by strand displacement synthesis at a constant temperature using the enzyme Phi29 polymerase, a high-fidelity enzyme. Hexamers (a chain of six random nucleotide sequences) are added to the DNA sample. After annealing of random hexamers (acts as primers) to the denatured DNA at various sites, Phi29 pol enzyme elongates the strand, and it also displaces the newly synthesized strand and continue its elongation. The enzyme performs strand displacement activity, thus forming new DNA by rolling circle amplification approach (Dean et al. 2001). Error rates are low ( $10^{-8}$ ) with phi29 DNA pol compared to *taq* DNA pol used in PCR-based WGA, and higher length fragment up to 100 kb can be amplified using these simple techniques. Now the displaced single-stranded DNA acts as a template for hexamer binding and formation of new displacement strand leading to a DNA network of increased yield. These networks will be cleaved using nucleases at the end of the process. The reaction happens at an isothermal condition around 30 °C, thus not requiring a thermocycler.

Chimeric formation is more in MDA techniques. Other techniques are the variations of non-PCR-based MDA.

## WGA in Diagnostics and Research

WGA products can be used for whole genome sequencing, genotyping, gene library development, microarray, organism identification, SNV & CNV identification, tumor heterogeneity by microsatellite analysis, percentage of genome amplification, to compare with other commercial kit results, archiving previous samples and in pre-implantation genetic testing. This basic technique is used to study the status of embryo for genetic defects from a single cell (contains 6 pg of DNA) before implantation during in vitro fertilization (IVF) (Wells and Delhanty 2000). WGA method can be selected according to the needs of the researcher. This paves a new way in rapid molecular detection of various diseases even from a single cell. In unculturable microbial communities from soil and water samples, MDA technique plays a major role in amplifying DNA.

## Limitations of WGA

An ideal WGA method should cover and amplify the entire chromosome representing the original genome with high fidelity and no contaminants. Multiple amplification errors and artifacts occur in real situations. This incomplete WGA results in problems like incomplete whole genome sequencing, missing copy number variants, chimeric formations, and incomplete allelic representation of the original genome. Choosing a perfect WGA method may reduce the challenges and holds promise in its utility toward research and medicine.

## Wilhelm Wundt

Yzar S. Wehbe and Todd K. Shackelford  
Department of Psychology, Oakland University,  
Rochester, MI, USA

## Preface

This entry relies heavily on the following three books: (1) *Wundt and the Philosophical Foundations of Psychology: A Reappraisal* (Araujo 2016), which provides a philosophical history of Wundt's ideas on psychology, (2) *Wilhelm Wundt in History: The Making of a Scientific Psychology* (Rieber and Robinson 2001), and (3) *The Story of*

*Psychology* (Hunt 2007). These three references substantially overlap on the facts about Wundt featured in this entry. Other references are cited as needed.

## Biography and Impact

Wilhelm Maximilian Wundt (1832–1920) was a German physiologist and psychologist generally known as one of the founders of scientific psychology. After earning a medical degree at the University of Heidelberg, and studying briefly with Johannes Müller, he was employed as a lecturer in physiology at the University of Heidelberg, where he became an assistant to the renowned physicist and physiologist Hermann von Helmholtz. While there, he authored *Beiträge zur Theorie der Sinneswahrnehmung* [Contributions to the Theory of Sense Perception] – published in 1862. In this book, he challenged the dominant ideas of the physiologists and philosophers of the time by arguing that the study of the psyche can be a science if done experimentally. Wundt also presented the first course on the topic of psychological science, which had been considered a branch of philosophy and had been studied primarily via rational analysis. Wundt turned his course of psychology into a book titled, *Lectures on the Mind of Humans and Animals*. His career spanned about 65 years, and he graduated 186 doctoral students. He was thrice nominated for a Nobel Prize. Wundt was extraordinarily prolific – his published work spans an estimated 53,000 pages (Kim 2016).

## Psychological Science's Beginnings

In 1879, at the University of Leipzig, Wundt founded the first official laboratory for psychological research, which became known as The Institute for Experimental Psychology. In 1881, he formed the first academic journal for psychological research, *Philosophische Studien* [Philosophical Studies], which published the institute's research. The institute attracted a large number of faculty and students who, in turn, became prominent figures in psychology across the

globe, including Emil Kraepelin, G. Stanley Hall, and James McKeen Cattell. His textbooks influenced the first two generations of American psychologists and their students, until the 1920s, when interest in Wundtian psychology began to wane. Wundt wrote on many subjects, despite his belief that most could not be adequately empirically tested. It was typical of Wundt to compare and contrast his ideas with those of other schools of thought, both new and old. For these reasons, Wundt could be considered an encyclopedist.

## The Wundtian Method

From the modest beginnings of physiological psychology, he created a unique methodology for psychology – one that served as a model for psychologists for decades. Wundt placed a notable emphasis on studies involving reaction time measurements. Although measurement of reaction time was already taking place in physiology, his examination of consciously organized temporal processing was a unique addition.

Wundt's favored methodology was introspection, or the inward examination of conscious experience. Wundtian introspection is more narrowly defined compared to how the term is often used today. Wundtian introspection involved observing the reactions of participants subjected to stimuli such as lights, colors, and sounds. Although Wundt had claimed in *Contributions* that the psyche could be studied empirically and quantitatively, he subsequently believed this to be true only for the basic elements of consciousness – sensations, perceptions, and feelings, as well as the associations among them. Helmholtz and others had conducted similar experiments, though these were limited to studying manifest behaviors. Wundt's contribution was the use of introspection to gather quantitative information about non-behavioral conscious experiences.

## Wundtian Psychology

Many of Wundt's theories and conceptualizations were subject to his own revisions, and many of the

major revisions involved the topic of volition. For example, three key propositions that he later abandoned or toned down were: (a) all mental acts are structured by logical rules, (b) unconscious processes are key, and (c) – linking the first two principles – the idea that the mind makes “unconscious inferences” by constructing more complex representations based on, for example, data from sensory perception. While Wundt appreciated that his theory of unconscious inferences had been adopted by Helmholtz, he did not agree with the manner of its application, since Helmholtz only used it to explain visual illusions, whereas Wundt had argued it to be essential for a psychological explanation of the perception of space. For more on the relationship between Wundt and Helmholtz, see the section titled “Wilhelm Wundt 1832–1920” in another entry in this encyclopedia “Hermann von Helmholtz” (Thomas [this volume](#), p. 14).

Wundt’s abandonment of these three propositions shaped his most influential text, *Grundzüge der Physiologischen Psychologie* [Fundamentals of Physiological Psychology], in which he argues that we need an account of the experiencer of psychology based on conscious experience. Wundt believed that even though immediate elementary experiences were caused by particular stimuli, conscious experience had its own type of causation – ideas that build on one another according to specific laws. Wundt named these laws, which were his conceptualizations of association, judgment, creativity, and memory. Actions resulting from more complex mental processes are acts of will or volition. Wundt believed that these volitional processes are the products of an experiencer who actively chooses to think, speak, and act in certain ways. While this theory no longer plays a key role in contemporary psychology, it was part of Wundt’s attempt to move away from the automatism of mechanistic psychology and toward what he regarded as a more complete model.

## Wundt’s Animal Psychology

Wundt considered animal psychology a fitting topic for ruminations, philosophies, and informal

experiments (including some that he lectured on featuring his poodle) but did not allow any work with animals in his laboratory because no data based on introspection could be obtained. In an idea reminiscent of Aristotle’s *Scala Naturae*, Wundt believed that humans are at the pinnacle of a progressive evolution, and that animals may therefore be helpful insofar as they represent a precursor to the human mind. In his autobiography, he commented that his studies of animals in the book *Lectures on the Mind of Humans and Animals* were superficial and that they had been included due to his interest in Darwinism at the time.

In Wundt’s *Völkerpsychologie* [People’s Psychology], a 10-volume nonempirical investigation of social psychological phenomena, he hypothesized that volitional mental processes reflected advanced evolution, and that these abilities are what render humans intellectually superior to other animals. Specifically, he argued that the human capacity for selective attention is what facilitated intellectual progress and the development of human culture. Without these abilities, Wundt believed that humans would be buffeted about aimlessly by sporadic thoughts, memories, and perceptions.

When Wundt first became preoccupied with explaining human and animal movement, the difference between action and movement prompted extensive research and debate with highly influential researchers such as Alexander Bain and Hermann Lotze. All three were indebted to the earlier work of physiologist Johannes Müller. Unlike Bain and Lotze, Wundt did not think that voluntary activity results from learning. What Wundt brought to this debate is a phylogenetic perspective indebted to Darwin’s theory of evolution. Wundt asserted that: “The intentional character of the reflexes then becomes easily intelligible, if we regard them as resulting from the voluntary action of previous generations” (Wundt 1894, p. 227).

It is not uncommon to see quotes from works by Wundt in which he communicated great appreciation for Darwin’s contributions, but when read in context, one finds that they are often followed by a rejection of a basic premise of Darwinian

evolution (that evolution is driven by blind forces that lack foresight) and instead endorse a view of evolution that accords with German idealistic philosophy (directed by teleological rather than mechanistic causal forces). For example, Wundt claimed that the theory of natural selection expresses a teleological rather than a causal principle, and that in calling variations on which natural selection operates “accidental,” Darwin had repudiated his own attempt at providing a causal explanation.

## Conclusion

Wundt’s writings reveal deep and wide-ranging interests (culture, art, law, language, history, religion) which have long been overlooked, partly due to the fact that most of his works have never been translated into English. A recent digitization of his corpus may revive interest in his vast collection of papers and books (Meyer et al. 2017). Wundt was not merely a compiler of volumes, despite popular descriptions that portray him this way. Less known facts about Wundt include his lack of adherence to a positivistic approach, his arguments for the idea that psychology and philosophy are intertwined, and importantly, his view that *Völkerpsychologie* (essentially, social psychology) is important and complementary to his individual-level psychology (Jovanović 2021). He is sometimes thought to have been overly restrictive in what he considered to be part of psychological science, barring many areas that are now commonly accepted as essential parts of the discipline. Yet Wundt had a more inclusive view of psychology than is often believed, as evidenced by his willingness to write about a broad range of topics even when he thought they could not be rigorously tested. Moreover, many of the methods now available in psychology and animal behavior simply did not exist during his time, which surely contributed to this view. While many of Wundt’s specific views may no longer be influential, he contributed a great deal to the establishment of modern psychology as an experimental, empirical science.

Wilhelm Wundt in 1902

[W.D. Hamilton](#)

### Definition

William Donald Hamilton (1936–2000) was a British evolutionary biologist famous for his work explaining social behavior through the framework of evolution by natural selection.

William Donald Hamilton (1936–2000), commonly referred to as W.D. Hamilton, was a British evolutionary biologist famous for his work explaining social behavior through the framework of evolution by natural selection. He is widely recognized as one of the most distinguished evolutionary theorists since Charles Darwin (Dawkins, 2000; Trivers, 2000). William Donald Hamilton was born on August 1, 1936 in Cairo, Egypt, to Archibald Milne Hamilton, an engineer, and B.M. Hamilton, a medical doctor (“W.-D. Hamilton,” 2020). As a child, he was interested in natural history and was introduced to the principles of evolution by natural selection and genetics by E.B. Ford’s *Butterflies* (1945) which would serve as inspiration for his later work (“W.-D. Hamilton,” 2020). He went to Tonbridge School in Kent, England, before attending University of Cambridge for his undergraduate education (Dawkins, 2000). Hamilton was jointly enrolled at University College London and

London School of Economics as a doctoral student (Dawkins, 2000). He married Christine Freiss in 1966 and they had three daughters before amicably separating 26 years later (“W.D. Hamilton,” 2020).

W.D. Hamilton presented his mathematical model for inclusive fitness when he was still a doctoral student in 1964 in two citation classic papers (Dawkins, 2000). He published the papers entitled “The Genetical Evolution of Social Behaviors I” and “The Genetical Evolution of Social Behaviors II” in the *Journal of Theoretical Biology*, presenting the concept now known as Hamilton’s rule (Hamilton, 1964a; 1964b). Hamilton’s rule posits that a gene for altruistic behavior will propagate if it satisfies an inequality. The inequality is  $rB > C$ , where  $r$  is the relatedness between the actor and recipient,  $B$  is the benefit to the recipient, and  $C$  is the cost to the actor. If the cost to the individual performing the altruistic act is less than the additional reproductive benefit to the recipient of the altruistic act multiplied by the genetic relatedness of the recipient and the actor, the gene for altruism will increase in frequency. Hamilton’s rule is a significant contribution to the study of altruism and provides a mathematical basis for inclusive fitness.

Although Hamilton’s rule was not globally recognized until decades after it was first published, Hamilton secured prestigious positions at Imperial College London, Harvard University, University of Michigan, and University of Oxford (Dawkins, 2000). While at Imperial College London, he published another citation classic entitled “Extraordinary Sex Ratios: A Sex-Ratio Theory for Sex Linkage and Inbreeding has New Implications in Cytogenetics and Entomology,” in which he introduced the concept of an unbeatable strategy (Hamilton, 1967). Hamilton’s unbeatable strategy served as inspiration for Smith and Price’s concept of evolutionary stable strategy, a strategy or set of strategies that cannot be replaced by an alternative competing strategy when adopted by a population in a specific environment (Smith & Price, 1973). In collaboration

with Robert Axelrod, Hamilton expanded the concept of evolutionary stable strategy to explain the evolution of cooperation among unrelated individuals as a result of reciprocity (Axelrod & Hamilton, 1981). Hamilton's work was instrumental in establishing the genetic basis of altruistic cooperation among related and unrelated individuals. His work was also foundational in advances in evolutionary perspectives of sex ratio, senescence, social insects, and dimorphic males (Trivers, 2000).

W.D. Hamilton's later work focused on parasites (Dawkins, 2000). He was an early proponent of the Red Queen hypothesis, arguing that parasites play a key role in the evolution of sexual reproduction in their hosts since sexual recombination provides a defense against rapidly and antagonistically coevolving parasites (Trivers, 2000). In collaboration with Marlene Zuk, Hamilton reported that healthier individuals of species of birds with higher loads of blood parasites have more colorful feathers and more complex song (Hamilton & Zuk, 1982). This finding demonstrates that parasite-rich environments foster preference for these traits and, therefore, that parasites play a pivotal role in mate choice and sexual selection. Hamilton was a skilled field researcher; he joined an expedition to the Democratic Republic of the Congo in 2000 to investigate the theory that the oral polio vaccine was the origin of the HIV virus in humans (Dawkins, 2000). While in the Congo jungle, Hamilton contracted malaria and was transported to London where he died on March 7, 2000 ("W.D. Hamilton," 2020). During his lifetime, Hamilton was awarded Fellowship of the Royal Society, the Kyoto Prize, the Fyssen Prize, the Newcomb Cleveland Prize, the Linnean Medal, the Sewall Wright Award, the Wander prize, and the Crafoord Prize (Dawkins, 2000; "W.D. Hamilton," 2020).

## William Hopkins

David A. Leavens

School of Psychology, University of Sussex, East Sussex, UK

### Title of Entry

William Donald Hopkins

### Introduction

William (Bill) Donald Hopkins is a Professor of Neuroscience in the Institute of Neuroscience, Georgia State University, Georgia, USA. Professor Hopkins has published over 310 journal articles, book chapters, and edited books. He specializes in functional asymmetries in brain organization and in behavior, especially in great apes, and has pioneered the use of noninvasive imaging techniques to directly measure details of brain organization, including both positron emission tomography (PET) and magnetic resonance imaging (MRI). Professor Hopkins has also made fundamental discoveries in communication dynamics in great apes, building on these findings to support an emerging new theoretical perspective on the evolution of language. Great apes are humans' closest living relatives in the animal kingdom, and therefore they serve as a scientifically important comparison group for the elucidation of the evolutionary changes that have occurred in the human lineage since we last shared a common ancestor with the great apes, approximately 7 million years ago.

### Biography

Bill Hopkins was born and raised on a dairy farm in Wisconsin, in September, 1959. He earned his Bachelor of Science degree in Psychology, at the University of Wisconsin, in Madison, Wisconsin. He travelled to Atlanta, Georgia, for graduate studies in psychology, earning his Master of Arts

(1986) and PhD (1990) in the Department of Psychology at Georgia State University. He began research early in his career, working at the Wisconsin National Primate Center as an undergraduate, and as a Research Assistant, then Associate Research Coordinator, and later, Research Associate at the world-famous Language Research Center (LRC), in Panthersville, Georgia, working with Duane Rumbaugh and Sue Savage-Rumbaugh as a graduate student. While working at the LRC, he became interested in the effects of language training on cerebral asymmetries and began his lifelong research program into handedness, particularly in great apes. Upon earning his doctorate, he embarked on two productive postdoctoral fellowships, first at the Centre Nationale de la Recherche Scientifique, Laboratoire de Neurosciences Fontionnelle, Unite de Neurosciences Cognitives, in Marseille, France (1991–1992), and then at the Laboratory of Comparative Ethology, National Institutes of Child Health and Human Development, in Bethesda, Maryland (1992–1993). Professor Hopkins has held numerous academic positions, teaching at Kennesaw State University (1993–1994), Emory University (1994–2002), Berry College (1994–2005), and Agnes Scott College (2006–2012) prior to joining Georgia State University in 2012.

Professor Hopkins holds senior research positions with the Yerkes National Primate Research Center (1989–present), the Language Research Center (1994–present), and the MD Anderson Cancer Center (2011–present) and has served as the President and Scientific Director of the Ape Cognition and Conservation Initiative near Des Moines, Iowa, since 2013. He is an Associate Editor for *American Journal of Primatology* and sits on the editorial boards of the journals *International Journal of Primatology*, *Primates*, and *Laterality*. His research has garnered over \$14,000,000 from such funding agencies as the National Institutes of Neurological Disorder and Strokes, the National Institutes of Mental Health, the National Institutes of Child Health and Human Development, the National Institutes of General Medicine and Science, the Human Frontiers Scientific Program, and the National Science Foundation, among many others.

## Laterality: Behavioral and Cerebral Asymmetries in Great Apes

In a pair of papers in 1989, Bill Hopkins began to challenge the then widespread idea that population-level right-handedness was unique to humans among primates. Because humans display both a population-level left-cerebral hemisphere dominance for language and right-handedness, many theorists at that time viewed right-handedness as an evolutionary artifact of our brain adaptations for speech (e.g., Warren 1980). Hopkins et al. (1989) reported significant right-hand biases for manipulating a joystick by two rhesus monkeys (*Macaca mulatta*) and three chimpanzees (*Pan troglodytes*) during computerized testing. They interpreted their findings as consistent with a growing recognition that human handedness is, in fact, sensitive to task context – it varies in degree with different kinds of demand. Hopkins and Morris (1989) reported a left-visual field (LVF) advantage for processing stimuli presented on a computer screen in two chimpanzees, suggesting a right cerebral hemisphere lateralization in visual processing in this species. Subsequent research revealed significant population-level right-handedness in chimpanzees in tasks involving fine motor coordination (Hopkins 1995, 1996, 2006).

Bill Hopkins pioneered the application of non-invasive brain imaging techniques with chimpanzees and used this technology to directly explore anatomical and functional asymmetries in chimpanzees and other primates. Using magnetic resonance imaging (MRI), he reported significantly longer left sylvian fissures in great apes (Hopkins et al. 2000); this is a deep cleft that separates the temporal lobe from the frontal and parietal lobes, and this asymmetry is concordant with that reported for humans. Cantalupo and Hopkins (2001) later reported a humanlike asymmetric Broca's area – larger in the left hemisphere – in chimpanzees; because chimpanzees have not evolved language, this finding suggests that Broca's area may have a functional organization that is evolutionarily grounded in communication and later co-opted for speech in humans. Recently, Hopkins has begun a series of studies into the

genetic underpinnings of behavior and brain asymmetries in primates (e.g., Gómez-Robles et al. 2016; Mahovetz et al. 2016). He has also discovered long-term effects of early rearing experiences on aspects of brain development in chimpanzees, demonstrating their value as animal models for human development (e.g., Bard and Hopkins 2018).

One domain in which chimpanzees seem to be particularly asymmetrical is in the display of manual gestures. Hopkins and Leavens (1998) reported that chimpanzees displayed a right-hand bias in their use of manual gestures and that, moreover, chimpanzees who vocalized while gesturing were more right-handed than chimpanzees who did not vocalize while gesturing; this suggested an integration of manual-vocal communication in this species, and the basic finding has been repeatedly replicated (e.g., Hopkins and Cantero 2003; Hopkins and Wesley 2002). In addition, he and his colleagues (Losin et al. 2008) discovered that the display of facial expressions during calling is asymmetrical in different directions, depending on the quality of the call – learned calls, typically used to capture the attention of a social partner, displayed greater expressive range in the right side of the face (left cerebral hemisphere), whereas more emotive, species-typical calls were expressed more strongly on the left side of the face (right cerebral hemisphere). Professor Hopkins published an edited book on laterality in 2007, inviting the major theorists on lateral asymmetries to summarize the state of the art (Hopkins 2007).

Taken together, these findings on functional cerebral organization in chimpanzees and other species spurred additional inquiry into the intentionality of chimpanzee signaling and supported a significant new theoretical stance on the evolution of language.

## Ape Communication

Professor Hopkins's interest in the flexibility of ape communication was manifested early in his career. In his master's thesis, he discovered that the vocal repertoire of Kanzi, a language-trained

bonobo (*Pan paniscus*), systematically differed from the vocal expressions of zoo-housed bonobos (Hopkins and Savage-Rumbaugh 1991). A fundamental theoretical dichotomy has existed between humans and animals: humans alone, it has been claimed, communicate intentionally. At present, there is considerable debate over what this claim means, both philosophically and behaviorally. However, there is a well-established research tradition in developmental psychology that documents the transition to intentional communication in humans: by the end of their 1st year of life, human infants typically develop tactics of communication that manipulate the people around them – for example, they begin to point to distant objects and events, and they simultaneously look at their social partners, as if they are monitoring the effect of their gestures. Bill Hopkins and his colleagues decided to apply those same criteria to the gestural communication of captive chimpanzees, and a series of significant findings emerged. First, chimpanzees point, too – and this finding directly refuted numerous claims to the effect that only humans point (e.g., Leavens and Hopkins 1998). Second, chimpanzees choose which sensory modality in which to communicate. If an observer is facing away from a chimpanzee, they are more likely to display an auditory signal, as if to attract attention to themselves, whereas if an observer is looking directly at the animal, they tend to rely on visual communication, such as gestures (Hopkins et al. 2007; Hostetter et al. 2001) – similar patterns were reported in open-field studies of young chimpanzees by Tomasello and his colleagues (e.g., 1994), and Hopkins and his colleagues confirmed the phenomenon of tuning communication to receiver state under experimentally controlled conditions. Third, like human children, chimpanzees display tactics of repair when their initial communication is not successful (Leavens et al. 2005). Fourth, chimpanzees learn some of their calls from their mothers, and this refutes yet another longstanding theoretical claim of human uniqueness (Russell et al. 2013). Fifth, these patterns of flexibility suggest that chimpanzees possess far more flexibility in their calling behavior than has heretofore been appreciated – this apparent voluntary

control of both calls and facial expressions poses significant challenges to theories of the evolution of language that seek continuity between human language and either primate vocalizations or manual gestures (Hopkins et al. 2011). This research demonstrates that humans' nearest living relatives, the great apes, share communicative capacities with humans; whereas twentieth-century theoreticians viewed these abilities for intentional communication as derived from human evolutionary adaptations for speech, these findings support a new vision of the origins of language in which many language properties are shared with apes.

## Evolution of Language

McNeill (1992) suggested that language was irreducibly multimodal. Research by Bill Hopkins is consistent with the idea that where continuity exists between apes and humans is not in purely vocal signaling, nor in gestural signaling, but in the fundamental multimodality of signaling in these species (e.g., Leavens et al. 2010; Tagliavola et al. 2011). This constitutes a significant new theoretical perspective. Previous theories viewed human language as a system elaborated on the vocalizations of primates, derived from observations of semantic-like vocal communication in primates (e.g., Dunbar 1996), or as a gestural system that was later adapted for speech, a theory derived, in part, from the manifest intentionality of gesture production in great apes (e.g., Corballis 2002); the suite of discoveries by Bill Hopkins in the multimodal dynamics of brains, behavior, and genes throughout development has contributed substantially to an emerging integrated theoretical approach to the evolution of language.

## William James

Lucas McGranahan  
Chicago, IL, USA

### Definition

“Father of American psychology” who pioneered a functionalist and Darwinian approach to the field, popularized the philosophical school of American pragmatism, and influenced the modern study of religion.

### Introduction: Life and Works

William James was born into an affluent family in New York City in 1842. He was the son of a minor philosophical author and brother of acclaimed American novelist Henry James. James studied to be a painter as a teenager but enrolled in Harvard's Lawrence Scientific School in 1861. He first studied chemistry but quickly switched to anatomy and physiology, which he used as a basis for studying medicine. His education included a naturalistic expedition to South America in 1865–1866, as well as a trip to study the new science of psychology in Germany in 1867–1868. James earned his medical degree from Harvard Medical School in 1869 and was hired by Harvard as Instructor in Physiology in

1872. He taught physiology, psychology, and philosophy at Harvard before retiring in 1907.

As a Harvard faculty member James was instrumental in establishing psychology as a professional discipline in the United States. Known as the “father of American psychology,” James taught the country's first physiological psychology course in 1875, supervised its first dissertation on a psychological topic in 1878, and published its first important treatise on psychology, *The Principles of Psychology*, in 1890. James's *Principles* is distinguished from prior psychologies by its “positivist” methodology, that is, its emphasis on observable correlations and eschewal of unobservable spiritual entities. This methodology, combined with its Darwinian perspective, makes it a distinctively modern psychological text. Along with its abridged version, *Psychology: Briefer Course* (1892/1985b), James's *Principles* was the key textbook in the field for a generation. Finally, James's psychology laboratory at Harvard, founded in 1875, was also arguably the country's first. (James's student G. Stanley Hall is sometimes given this honor for his later, but more advanced, laboratory at Johns Hopkins University.)

Although *The Principles of Psychology* made James a respected academic, he was also a radical, eclectic, and popular thinker. During the 1890s, James distanced himself from laboratory psychology and championed the study of esoteric abnormal psychology and paranormal phenomena. At the same time, he increasingly lectured on philosophical topics such as truth, metaphysics, and religion. His 1897 book *The Will to Believe* defends the right to hold certain improvable beliefs, and his 1902 book *The Varieties of Religious Experience* is a seminal text in the psychology of religion.

In the final stage of his career, James elaborated his metaphysical doctrine of radical empiricism, which holds that minds and their objects are functions of a more basic reality that is neither objective nor subjective. In parallel, he put forth his philosophy of pragmatism, which holds that the meaning of a concept consists in its practical effects, such that true ideas are just those that “work” in experience. Pragmatism was further

developed by another American psychologist and philosopher, John Dewey, who made it the dominant philosophical school in the United States through the end of World War II.

James died of heart failure in 1910, having achieved international fame in multiple fields of study.

## An Education in Evolution

Evolutionary biology was formative for James in several ways. First, James matriculated at Harvard soon after Darwin published *On the Origin of Species* (1859), introducing the theory of natural selection, or evolution by the differential survival and reproduction of different organisms with different heritable traits. James learned about Darwin's theory from leading scientific minds at Harvard, such as zoologist Louis Agassiz, botanist Asa Gray, and anatomist Jeffries Wyman. James even accompanied Agassiz on an expedition to South America, although he ultimately rejected the latter's dogmatically anti-Darwinian position.

Second, James belonged to the storied "Metaphysical Club," a discussion group that centered on Harvard in the 1870s and included seminal American philosopher Charles Sanders Peirce and future US Supreme Court justice Oliver Wendell Holmes, among other luminaries. Evolutionary debates were central to the Metaphysical Club, with philosopher Chauncey Wright in particular pushing James toward Darwinism. Wright published little himself, but he was an important forerunner of James's Darwinian psychology (1873).

Third, James discussed the topic of evolution from the very outset of his publishing career. This includes anonymous reviews of Darwin's supporter Thomas Henry Huxley, natural selection's co-discoverer Alfred Russell Wallace, and Darwin himself. James also applies Darwinian concepts to the study of human psychology and history in his earliest signed scholarly essays beginning in the late 1870s. Finally, and most importantly, James boldly supports natural selection in his *Principles of Psychology*, an impressive survey of the

burgeoning science of mind that he wrote between 1878 and 1890.

## From Lamarckism to Darwinism

Darwinism was not taken for granted in psychology during James's time. Darwin's principle of natural selection did not achieve its current status as an essential biological principle until the 1930s, when it was integrated with Mendelian genetics and defended using new statistical methods. James's advocacy for natural selection therefore occurred during a period of uncertainty for the theory, as it competed against other evolutionary and nonevolutionary accounts of mind and life.

A case in point is English writer Herbert Spencer (1820–1903). Spencer was the most important evolutionary psychologist prior to James. Indeed, Spencer published his evolutionary theory prior to Darwin's, which ultimately included an evolutionary account of mind, life, society, and the cosmos as a whole. It was Spencer who familiarized the general public with evolutionary ideas, coined the phrase "survival of the fittest" (for Darwin's theory), and gave currency to the very words "evolution" and "environment."

The first edition of Spencer's *Principles of Psychology* (1855) in particular represents a key compromise between two traditional philosophical views: one that grounds knowledge in innate cognitive structure (as in Immanuel Kant) and another that traces knowledge to the acquired sensory experience of the individual (as in David Hume). Mind for Spencer is innate at one level but acquired at another: Innate structure derives from evolutionary processes, and the individual builds upon this structure during development. Such a compromise, broadly construed, is taken for granted in psychology today.

What is not taken for granted is Spencer's preferred evolutionary mechanism. Following Jean-Baptiste Lamarck (1809), Spencer posited evolution by the inheritance of acquired characteristics. This means invoking the population's *collective transformation*, whereas natural selection invokes its *selective sorting*. To use a classic

example, Lamarck explains the giraffe's height in terms of the parallel (and heritable) efforts of all giraffes to stretch their necks, whereas Darwin explains this trait by the survival and reproductive success of those giraffes lucky enough to be taller than average. Similarly, according to Spencer, mind evolves as individuals continually get better at mapping the complex external world and pass on these cognitive gains – physiologically, not just culturally – to their offspring.

Lamarckism and natural selection are compatible in principle. In fact, both Spencer and Darwin accepted both mechanisms, while disagreeing about their relative importance. In contrast, James prefigures twentieth-century biology by rejecting Lamarckism completely in the final chapter of *The Principles of Psychology*. Here James argues that natural selection can explain any trait explained by Lamarckism, and indeed that Darwinian nondirected variation must have been present in cognitive evolution (in contrast to Spencer's tenet that evolution is linear and fated). Additionally, James favorably cites German biologist August Weismann, whose theory of heredity prefigured the "central dogma" of twentieth-century genetics by denying that information can flow back to the genetic material during development in a systematically adaptive and heritable fashion. James concludes that natural selection is necessary for explaining mental evolution but that Spencer's Lamarckism is neither necessary nor plausible. This made James the first important psychologist to adopt an overtly Darwinian (and non-Lamarckian) approach.

## The Emotions

One of James's most cited positions is his theory of the emotions. During the 1880s, James and Danish physician Carl Lange independently formulated a similar account of the nature of emotion. An intuitive or commonsense view holds that an emotion is a mental perception or judgment, upon which certain recognizable physiological changes may follow. James reverses this logic:

My thesis on the contrary is that *the bodily changes follow directly the PERCEPTION of the*

*exciting fact, and that the feeling of the same changes as they occur IS the emotion.* . . . the more rational statement is that we feel sorry because we cry, angry because we strike, afraid because we tremble. (1884, pp. 189–190).

James thus contends that emotions *just are* the experience of certain physiological changes. Upon seeing a bear on a hiking trail, one's fear consists in one's perception of certain physiological "fight or flight" responses, after these responses had already been triggered. James's position on the emotions, in combination with his general skepticism of dichotomies such as emotion/reason and mind/body, prefigure the idea of embodied cognition that arose toward the end of the twentieth century.

A critique of James's position is that the same bodily states may correlate with different emotions, or that different people may express the same emotions differently. This suggests that an emotion is a cognitive judgment preceding the relevant physiological changes. According to James, however, if emotion were defined solely in cognitive terms, this would mean that one could experience an emotion without any given set of bodily sensations. Such an intellectual definition of emotion is too bloodless and spectral, on James's view.

## Reflex Action, Will, and Freedom

Central to James's psychology is the nineteenth-century physiological conception of the "reflex arc" or "reflex action." According to this model, the sensorimotor system comprises an arc or – as John Dewey (1896) would insist – a *circuit* in which sensation, cognition, and behavior are defined in terms of their functional interrelations. A nervous impulse is triggered by a sensory stimulus, which in turn triggers cognitive processes that discharge in an associated action. Sensation and cognition are in this sense *for* action. This is a source of James's notion that belief, truth, and knowledge should be understood as essentially practical in nature.

James portrays the entire reflex arc as a hierarchical series of filters that each sort material

provided by the layer beneath: Sensation selectively registers stimuli from the external world; perception selectively eliminates and foregrounds certain features of objects; cognition selectively emphasizes various aspects of situations or ideas for logical, practical, and aesthetic purposes; and the will is capable of selecting among possibilities for action.

This last point is key to James. Reflex action may occur automatically along neural paths of least resistance, in which case it is called “ideo-motor action.” James denies that all action is ideo-motor, however, because he contends that individuals can actively bias their actions through acts of will: Options for action filter up from lower levels of perceptual and cognitive processes, and one selects an option by attending to it such that its associated motor consequences automatically follow.

James denies that the will’s selections are pre-determined, and in this sense he believes the will to be free. (He considers this position to be neither provable nor disprovable, empirically.) James intends this position as an explicit rejection of the “conscious automaton theory” of his time, which claimed that human consciousness has no efficacy in the world. According to Thomas Henry Huxley, for instance, consciousness is like steam escaping from a train whistle, which does not reach back down into the engine to do any work. James denies this. However, his concept of free will is a constrained one, since it does not allow the individual to invent behaviors wholesale.

Interestingly, selection appears in this story at multiple levels and timescales. First, James argues that conscious awareness would not exist if it did not serve some evolutionary function. James thus makes a Darwinian argument for individual agency, which is ironic given Darwinism’s reputation as an inhuman and mechanistic view of nature. Second, the will’s function in development is similar to that of the environment on Darwin’s theory, since it is capable of selecting possibilities but not creating them. The same is true of each level of selection in the reflex arc, since each merely filters material provided from elsewhere. Finally, the entire reflex arc generates behavioral variation that is tested out against the external

world. It was James’s student Edward Thorndike who proposed the “law of effect,” that is, the tendency of behaviors to be repeated if they produce a satisfying result (1898). This law provided a formal basis for behaviorist theories of reinforcement or conditioning that became dominant in the twentieth century.

James consistently argued that individuals have agency within their own lives and within the social and natural environments that embed them. Like his godfather Ralph Waldo Emerson, James is known as a classic American individualist. Unlike Emerson, however, he defended this position from a physiological and Darwinian perspective. In particular, James framed his position in contrast to Herbert Spencer’s view that both ontogeny and phylogeny are processes of coercive molding in which organisms are shaped by an autonomous environment. James argued instead that organisms co-construct their environments in evolution and that humans similarly co-construct their societies in history (James, 1897/1979, pp. 163–195).

Darwin’s great conceptual advance, according to James, was the idea of variation that is produced *for no environmental reason*. Natural selection thus drives a logical wedge between organism and environment – a wedge that does not exist for the Lamarckian who construes adaptations as direct responses to environmental demands (James 1897/1979, p. 168). For James, this non-directed variation was emblematic of the idea that nature may contain relatively independent systems that interact in a complex fashion without any one factor completely controlling the output. In contrast, many neo-Darwinians are closer to Spencer in viewing evolution as a process of coercive environmental shaping in which individual organisms play a negligible role.

## Habit, Morality, and the Self

According to James, the essence of moral action is the selection of behaviors that restructure one’s habits in the direction of an ideal self. Inspired by the moralistic physiological writings of Alexander Bain and William Benjamin Carpenter, James

portrays the self as a plastic bundle of habits that can be altered through the strengthening or weakening of nervous channels. The habitual structure of the self then becomes a long-term artistic and ethical project. The goal of this project, in James's words, is "to make the nervous system our ally instead of our enemy" (James, 1890/1981, p. 126).

In this context, instinct can be viewed as a special kind of habit. James is known for having posited a great number of human instincts – and even for claiming that humans have more instincts than other animals – but he operated with a somewhat deflated concept of instinct. An instinct for James is just a seemingly goal-oriented behavior that did not have to be learned. Strictly speaking, it is only an instinct upon first exercise, at which point it takes its place as a plastic habit among others. It need not even be immutable or universal within a species.

James describes habit as an essentially conservative agent. This has advantages: The batter in baseball swings more efficiently when the relevant sequence of muscular contractions fires off in an unconsciously associated chain. On the other hand, the conservative nature of habit also means that one constantly finds oneself stuck in what mappers of evolutionary space call a "local optimum" – an adaptive state that has proved good enough or better than readily available alternatives, but which could be surpassed.

The continual surpassing of locally optimal habitual states is thus available as a goal for moral self-cultivation. James promotes his vision of moral development in *The Principles of Psychology* (1890/1981) and in his pedagogical lectures *Talks to Teachers on Psychology* (1899/1983). The key difference between these texts is that in the *Principles* James focuses on how one can direct one's own development, whereas in *Talks to Teachers* he focuses on how teachers can inculcate useful habits in their students.

Although James's pedagogical theory focuses on the shaping of students' behavior, it should not be conflated with the behaviorism that overtook psychology after his death. Behaviorism is essentially "outside-in" in its explanatory structure: External stimuli cause behavior through a process

of conditioning. In contrast, James critiqued an excessive emphasis on external factors, positing complex feedback between individuals and their environments. According to James, individuals are inherently idiosyncratic, spontaneous, and capable of making free choices. He thus believes that education requires intuitive social and emotional skills, not just rule-based conditioning.

James thus construes the self as a plastic bundle of habits that is structured by a reflex arc and mediated by a selective will. Such a self is subject to education and moral improvement. James also sketches several further layers of the self that go beyond physiological psychology: the material self, including one's body, clothes, property, and the fruits of one's labor; the social self, defined by one's recognition from others; the pure ego, which may be a soul or transcendental source of identity; and the spiritual self, defined by one's direct experience of the stream of consciousness.

## The Stream of Consciousness

The stream of consciousness – called "the stream of thought" in *The Principles of Psychology* – is one of James's most influential concepts. According to James, introspection reveals five key characteristics of conscious experience. Thought is (1) always part of a personal consciousness ("my thought"); (2) always changing; (3) continuous; (4) always dealing with objects other than itself; and (5) always interested in some features of its objects more than others. Consciousness is a continuous, ever-changing flux that gives rise to selectively biased thoughts, images, and feelings. This flux, while experienced as "mine," always posits objects that transcend it. This analysis of subjective awareness has influenced both popular culture and the European philosophical tradition of phenomenology – the study of the essential structure of consciousness – including its founder Edmund Husserl.

Notably, the phrase "stream of thought" reflects the third characteristic of consciousness. James's point here is that thought is like a *stream* rather than a *train*. Experience may be analyzable into discrete ideas, feelings, and images, but this

does not mean that such elements are the constituent building blocks of experience. On the contrary, James argues that such “simple ideas” posited by classical empiricists are actually refined products of abstraction. James instead likens consciousness to a continuous flux out of which a tissue of mental elements and their relations resolves. In this stream of consciousness, the transitive “flights” of experience (feelings of logical, spatial, or temporal relation) are just as real and just as basic as the substantive “perchings” (abstract concepts and perceived objects), although the mind tends to suppress the former and foreground the latter (James, 1890/1981, p. 221).

James’s analysis of the stream of consciousness includes an influential account of temporality or the experience of the passage of time. According to James, the experience of the present moment has a structure in which one senses a stretching forward into the future and a simultaneous stretching backward into the past. James calls this the “specious present” (James, 1890/1981, p. 573). For James, the idea of an instantaneous present moment standing precisely between the future and past is a mathematical fiction that is never experienced in actuality. This means that the continuously flowing stream of consciousness is not anchored to a precise, isolable present moment.

## Radical Empiricism

James considers his doctrine of radical empiricism to be essential to his philosophical vision. This doctrine comprises several philosophical principles. The first principle is “fallibilism” or the view that all beliefs are subject to correction by future experience. Fallibility is a familiar concept within the philosophy of science, but James applies this principle broadly to entire philosophical and metaphysical worldviews. One’s very concept of the nature and function of science, for James, should be open to correction by experience.

The second principle is “pluralism.” On this view, the entire universe cannot be known in a single cognitive act, even in principle. Knowledge

is inherently piecemeal, and the world contains systems that hang together in a loose and indeterminate fashion rather than cohering in a fully rational, deterministic matrix. James’s father had been among the “monists” who oppose this view, arguing that the universe is a coherent and self-developing rational whole. This was a common position among idealist philosophers who developed aspects of the writings of Immanuel Kant during the nineteenth century.

The final principle of radical empiricism is that philosophy must be grounded in direct experience. As in his account of the stream of consciousness, James considers both discrete objects and the relations among them to be equally matters of direct experience. Reality for James is a flux rather than a set of independently existing beings. In particular, James denies that a permanent and stable thinking entity is accessible to experience. He thus concludes that “consciousness does not exist” (1976/1912), which is his provocative way of stating that the *transcendental* consciousness posited by certain philosophers does not exist.

The very subject-object distinction for James is a derivative function of a more basic reality called “pure experience.” Knowledge then consists of functional relations within pure experience. This position dissolves a basic philosophical dichotomy between the knower and the independent object that it knows. In doing so, it sidesteps a basic problem for traditional accounts of cognitive representation: How does one corroborate the mind-independent nature of objects if they can be only known through some act of knowing or other? James’s position also introduces puzzles, however, such as how two minds could possibly know the same object if it did not exist independently prior to any act of knowing.

## Religion and the Will to Believe

James was a prominent scholar of religion, most famously in his *Varieties of Religious Experience* (1902/1985a). James’s *Varieties* is not a study of religious dogma or institutions but of religion as experienced by the individual. Moreover, James understands religion very broadly, as one’s overall

way of relating to the universe. He spends much of the *Varieties* describing a series of religious personality types, arguing finally that the “saintly” type – defined by altruistic love and a sense of merging with a higher power – represents the ideal personality. James’s discussion of religious conversion in the book influenced the recovery philosophy of Alcoholics Anonymous. The book also introduced James’s concept of a “moral equivalent of war” or the idea of enlisting youth into civic projects rather than the military, which influenced Depression-era public works projects and the Peace Corps in the United States.

James was not just a scholar of religion but one of its defenders. In particular, he argued consistently throughout his career that it is sometimes permissible to hold religious beliefs in the absence of evidence. James likens belief to a bet that one is free to undertake at one’s own risk. For instance, he argues in his essay “The Will to Believe” (1897/1979) that an improvable belief may be justified if (1) the belief is psychologically possible, (2) the question is logically forced or unavoidable, and (3) the result has momentous consequences. James thus contends that a religious belief may be warranted if it creates a shift in one’s moral energies for the better. He also argues, using a similar logic, that one is entitled to believe that the world is morally improvable, if only because this belief may encourage the improvement of the world.

James thus viewed religion and belief in general in terms of their functions within the broader scope of human concern. He formalized this outlook in his philosophy of pragmatism.

## Pragmatism

James was the chief popularizer of pragmatism, America’s first philosophical school of international consequence. James’s pragmatism comprises a theory of meaning and a theory of truth.

James adapts his theory of meaning from Charles Sanders Peirce. Peirce defined the meaning of an object in terms of its conceivable practical effects (1878, p. 293). James takes “practical effects” in a very broad sense, including

dispositions for action. Thus, James defines the meaning of an object – or theory or worldview – by its conceivable effects on sensation, cognition, and behavior. He also claims that a dispute between competing theories is meaningless unless there is a “difference that makes a difference,” that is, a conceivable difference in someone’s experience if one were true rather than the other.

James’s theory of meaning underlies his pragmatist theory of truth (which James called “humanism”). On this view, a belief is true to the extent that it “works,” where any number of factors – including but not limited to traditional scientific verification – may contribute to a belief’s working. Thus, meaning consists in practical effects, and truth consists in having good practical effects. This is a highly unorthodox position within the philosophical tradition, as it treats “truth” as an umbrella term for beliefs that turn out to be useful, rather than an *explanation* for why a belief is useful.

As with James’s doctrine of the will to believe, pragmatism is sometimes accused of promoting wishful thinking. The pragmatist would seem entitled to believe anything that sounds good. However, James underscores the essentially conservative nature of individual and social belief systems, which holistically constrain our beliefs. He also claims that truth is inherently open-ended and historical – that is, fallible – such that we can never claim to have arrived at a final or absolute truth. James takes the long view, and he spurns dogmatism in all of its forms.

To say that truth is historical for James is not merely to say that we discover different truths at different times. More radically, it is to say that truth itself is inherently dynamic rather than static. In James’s words, “Truth happens to an idea. It becomes true, is made true by events. Its verity *is* in fact an event, a process: the process namely of its verifying itself” (1907/1975a, p. 97). James thus collapses the conventional philosophical distinction between truth (a static relation between a knower and known) and justification (a temporal process in which truth is discovered). A belief’s truth for James *is* its justification.

Both mind and truth evolve, on James’s view. Whereas in *The Principles of Psychology*

(1890/1981) James describes the biological evolution of cognition, in *Pragmatism* (1907/1975a) and *The Meaning of Truth* (1909/1975b), James portrays truth as undergoing its own social or cultural evolution. This is not simplistically to identify truth with those beliefs that support Darwinian fitness. Rather, James views truth as having its own selection process that is driven by a host of human purposes going beyond survival and reproduction.

## Conclusion

William James ushered in a physiological, Darwinian, and functionalist approach to psychology. James's central philosophical concept, however, was the reality and value of individual agency. James thus approached science from a humanistic and explicitly moral perspective. Indeed, Darwinism for James signified a scientific vindication of individual freedom, based on the premise that consciousness would not have evolved by natural selection if it had no efficacy in the world. The will for James is a name for consciousness's function of selecting ideas that represent possible actions. These selections are capable of altering both the external environment and the internal habitual structure, and the individual may undertake this process with a goal of moral self-cultivation.

This process of moral development also provides the framework in which James understands belief, religious or otherwise. His philosophy of pragmatism follows this lead, construing meaning and truth in terms of a range of practical effects. Evolution here appears at multiple levels in James's thinking, both as the origin of our cognitive powers and as a process of social evolution in which truth itself is developed according to myriad values and ideals. Darwin's principle of non-directed variation also inspired James to think of nature in general as a collection of indirectly related complex systems rather than a rationally comprehensible whole. James's radical empiricism is comprised by such a principle of pluralism, in combination with a fallible approach to

knowledge and a commitment to grounding theory in direct experience.

In short, the twin lessons of Darwinism for James are the reality of individual agency and the fallible and piecemeal nature of knowledge. On James's view, the world and human knowledge are *in the making*, with individuals as active participants.

## William Roberts

Neil McMillan  
University of Alberta, Edmonton, Alberta,  
Canada

Dr. William (“Bill”) A. Roberts is an internationally renowned experimental psychologist and Emeritus Professor at Western University (London, Ontario, Canada). Born in Safford, Arizona (USA), Bill completed his Bachelor of Science at the University of Maryland in 1960 and his Masters of Arts in 1962 and Ph.D. in 1965 at Bryn Mawr College, Pennsylvania, under the supervision of Dr. M.E. Bitterman. Bill was briefly a faculty member at Vassar College, New York,

before moving to Canada, first as a postdoc with Dr. Endel Tulving at the University of Toronto from 1968 to 1969 and then as a faculty member at Western starting in 1970.

Dr. Roberts has authored over 160 publications, including well-regarded books such as *Processes of Animal Memory* (Medin et al. 2014) and *Principles of Animal Cognition* (Roberts 1998) and highly cited articles such as “Are animals stuck in time?” (Roberts 2002). Dr. Roberts has studied a wide variety of cognitive processes in animals, including metacognition, time and number representation, memory, future anticipation, and transitive inference. His study subjects have been likewise varied and have included humans, rats, pigeons, dogs, horses, and squirrel monkeys. Dr. Roberts’ early work was pioneering in the field of animal memory processes, especially in the use of delayed matching-to-sample to study working memory (e.g., Roberts 1972; Roberts and Grant 1974, 1976, 1978). Some of his best-known recent work includes the comparison of time and number representations in pigeons (e.g., Roberts 2006; Roberts and Boissvert 1998; Roberts et al. 1989, 2000; Roberts and Mitchell 1994), mental time travel in monkeys, chickadees, and rats (e.g., McKenzie et al. 2004; Naqshbandi and Roberts 2006; Roberts 2007, 2016; Roberts et al. 2008; Roberts and Feeney 2009), and the competition between working and reference memory processes (Roberts et al. 2015, 2016).

Dr. Roberts has held uninterrupted grant funding from the Natural Sciences and Engineering Research Council of Canada (or, previously, the National Research Council Canada) since 1969. Since his retirement in 2004, Dr. Roberts has maintained a highly active lab, with many publications in top-tier journals in animal cognition as well as publications in high-impact journals such as *Trends in Cognitive Sciences*, *Current Biology*, and *Science*. He has been Editor for the journal *Learning & Motivation* since 2000. His research has also been highlighted in a number of newspaper and other popular media, including a large segment in a 2015 episode of *The Nature of Things*, *A Dog’s Life*. He has previously been Chair of the Department of Psychology at Western University and is a Fellow of

Divisions 3 and 6 of the American Psychological Association. Dr. Roberts was also honored with the Comparative Cognition Research Award in 2005 from the Comparative Cognition Society (of which he is a founding member) for his lifetime of achievement in the field.

## William Timberlake

### Timberlake

Evan Arnet  
Indiana University Bloomington,  
Bloomington, IN, USA

William “Bill” Timberlake (1942–2019) was a comparative psychologist and animal behavior researcher who achieved key experimental and theoretical findings through his integration of ecology and ethology into learning theory (Arnet 2019). He explored a broad array of topics but is best known for his work on response deprivation and reinforcement and a leading version of the behavior systems approach to animal behavior. Timberlake was a frequent critic of strictly operational approaches, and many of his contributions drew from his emphasis on the organism’s motivational structure, and how this structure would lead to behavior in varying contexts. His work alongside other ecologically influenced psychologists like Michael Domjan, Sara Shettleworth, and Bennett Galef helped to expand comparative psychology into animal behavior studies more broadly. Nonetheless, throughout his career Timberlake emphasized the value of comparative psychology’s focus on learning. In addition to his research contributions,

Timberlake was a founding member (alongside the biologist Ellen Ketterson) of Indiana University Bloomington's esteemed Center for the Integrative Study of Animal Behavior (CISAB). Much of this entry is informed by Arnet (2019), and the reader is referred there for a more detailed discussion of Timberlake's life and works (as well as the festschrift in *Behavioural Processes*, The Legacy of William Timberlake, of which it is part).

Timberlake was born in San Francisco to William B. Timberlake and Louzelle Spradling Timberlake. He excelled in school and ultimately went to Pomona College where he studied psychology. He started his graduate work in psychology at the University of Michigan in 1964, where he gained a substantial background in neoHullian behaviorism. His advisors, David Birch and Edward Walker (added later as co-advisor), were both part of an innovative group of motivation researchers at Michigan. This group, while still studying motivation from a behavioral as opposed to physiological or neurological perspective, was nonetheless challenging standard stimulus-response approaches (e.g., Birch and Veroff 1966). Rather than emphasizing only the role consequences of actions played in motivating behavior, they increasingly looked to the existing motivations of the organism as playing an important role in the relationship between stimulus and response. Influenced by Birch and others, Timberlake began to conceptualize behavior not as something atomistic that is induced in response to discrete environmental triggers but instead as a constantly generated stream of activity dependent on both internal motivation and environmental context.

Timberlake's dissertation emphasized the importance of first mapping an organism's general behavior to interpret the animal's behavior under intervention. He drew heavily from ethology for his dissertation, but rather than observing an animal in the wild, he observed and coded general behavior in the laboratory context. He made his long-term vision clear in his dissertation proposal: the articulation of the motivational structure behind an organism's behavior (Arnet 2019). His final dissertation was somewhat narrower,

focusing on detailed coding of the general behavior of the rat when allowed to behave freely in the laboratory. In 1969, Timberlake joined the department of psychology at Indiana University of Bloomington where he remained as an emeritus professor until his death in 2019.

At Indiana, Timberlake worked with the comparative psychologist James Allison, another former student of David Birch, to develop the core insights of Timberlake's dissertation into a still leading account of reinforcement—response deprivation. Response deprivation built on David Premack's influential relativity theory of reinforcement (for a history of reinforcement theories, see Adams 2000). Premack had argued that a more probable behavior would reinforce a less probable behavior, where probable is understood in terms of the relative duration an animal will engage in a behavior when allowed to behave freely (Premack 1965). Contra Premack, Timberlake and Allison found any behavior could serve as a reinforcer as long as an organism had a non-zero baseline probability of engaging in a behavior when allowed to behave freely, and the organism was deprived of that behavior (Allison and Timberlake 1973, 1974; Eisenberger et al. 1967). The implications, e.g., that water will motivate a thirsty animal differently from a satisfied animal now seem surprisingly intuitive but were a break from existing theory. Unlike previous approaches, which centered reinforcement in the experimental setup (most famously Skinner's reinforcement theory), the response deprivation theory of reinforcement centered on the animal and its motivational structure with respect to the specific environmental context it is occupying for the understanding of reinforcement. Timberlake further developed the response deprivation account of reinforcement into his disequilibrium theory (Timberlake 1980). This approach envisions an animal, when allowed to behave freely, as a system at equilibrium. Behavior modification occurs when the system is pushed out of equilibrium, and a response is required to return it to equilibrium. This approach shows considerable promise for applied behavior modification and clinical application (Jacobs et al. 2019; McFall et al. 2019).

An emphasis on the animal – its motivational structure, its ecology, its sensory abilities, its internal rhythms, and its natural behaviors – is characteristic of Timberlake’s approach throughout his career and is central to his most prominent findings. At around the same time as the work on reinforcement, Timberlake and an undergraduate student, Douglas L. Grant, did now celebrated experimental research on auto-shaping (Timberlake and Grant 1975). Their innovative experimental design used a live rat as the predictive stimulus for food for another rat. In contrast to the prevailing expectation, in which the subject rat would literally treat the predictive rat as food, trying to eat it, the subject rat instead exhibited the social behaviors associated with feeding. Timberlake and Grant interpreted this as the predictive stimulus tapping into an existing motivational structure. Relatedly, Timberlake et al. (1982) found that failures of reinforcement, memorably called misbehavior by Breland and Breland (1961), are not arbitrary, but rather often occur when the similarity of the stimulus to natural cues would unintentionally elicit natural behavior. This research challenged the very possibility of a neutral stimulus, or a stimulus that modifies behavior in no way beyond focusing attention (Domjan 1997).

Similar themes are present in his work on superstition, where Timberlake took on the legacy of B. F. Skinner. Skinner had observed if pigeons were fed at regular intervals, they began to exhibit structured repetitive behavior, such as spinning around (Skinner 1948). He argued these stereotyped behaviors were the product of random movements and behaviors being unintentionally “rewarded” by the food. Skinner famously described this behavior as “superstitious” behavior after our own structured and repetitive but ultimately misguided actions. Timberlake, building on the work of Staddon and Simmelhag (1971), clarified that the so-called superstitious behaviors were being drawn from the organism’s existing system of feeding behavior.

Beginning in the late 1970s, Timberlake sharpened the importance of an organism’s motivational structure into his behavior systems approach (Timberlake 1993). Behavior systems

approaches have at their core the ethological insight that organisms possess a hierarchically structured system of behaviors shaped by ecology and evolution (see Burghardt and Bowers 2017). Timberlake was one of the first to bring this approach into the laboratory. In contrast, to many ethologists who saw laboratory behavior as artificial, Timberlake viewed laboratory behavior as springing from the same underlying motivational structure (behavior system). Moreover, the controlled conditions of the laboratory were an ideal vantage from which to view the architecture of behavior systems. Against more operational approaches, Timberlake argued that blindness to the organism’s motivational structure, that is to say, assuming the organism was a blank slate that behaved at the whim of laboratory protocols, was leading to experimental and theoretical deficits in learning theory. For example, Timberlake’s research on maze running in rats exposed that rats learn maze running even in the absence of a reinforcer and challenged the purported neutrality of these approaches (Timberlake 2002).

Timberlake’s behavior systems framework has been at its most successful in resolving problems for classical learning theory, e.g., misbehavior, reinforcement, auto-shaping, superstitious behavior, and backward conditioning (see Arnet 2019; Killeen 2019). Nonetheless, the behavior systems research program that Timberlake pursued was not simply about the abstract importance of an animal’s motivational structure in understanding learning, but rather about articulating the structure itself in specific organisms and exploring how it leads to particular behaviors in various contexts.

Above all, Timberlake fought to put the animal back in the study of animal behavior. In a self-conscious spin on anthropomorphism, Timberlake referred to his overarching approach as Theromorphism (which he modified from the Greek word *Therio* for animal). Theromorphism differs from strictly empiricist approaches like radical behaviorism insofar as it takes the explanatory relevance of the animal seriously, but it seeks to describe the perspective of the animal not through analogy to the human mind, but rather through known facts about the sensory capacities

and motivational structure of the animal itself. Timberlake's Theromorphism calls for both a broader and a narrower comparative psychology. It is broader in that it demands the ecological and evolutionary variability of life be reflected in our science of behavior. But it is narrower, in that the understanding of behavior is rooted in a detailed analysis of particular behavior systems and not in generalized learning mechanisms. His legacy is most clearly reflected in the continued application of behavior systems approaches (Burghardt and Bowers 2017; Bowers and Timberlake 2018; Domjan 2014; Cabrera et al. 2019) and the use and development of the disequilibrium theory of reinforcement for behavior analysis and modification (Jacobs et al. 2019; McFall et al. 2019).

## Wisconsin Card-Sorting Task

Jennifer Vonk

Department of Psychology, Oakland University,  
Rochester, MI, USA

### Synonyms

[Attentional set-shifting test](#); [Conceptual set-shifting task \(CCST\)](#); [WCST](#); [Wisconsin card-sorting test](#)

### Definition

The Wisconsin card-sorting task (WCST) presents the subject with stimulus sets containing one to four shapes (stars, crosses, triangles, and circles) in four colors (red, yellow, green, or blue). In the traditional task, the subject is presented with four cards and asked to match a response card. The subject has to infer the matching rule (shape, color, and number) based on feedback from the experimenter. The rule continually and randomly changes. Recent versions are typically computerized, such as the conceptual set-shifting task (CSST, Moore et al. 2005). In this task, selection of the stimulus exhibiting a single attribute (e.g., color green) is rewarded regardless of the number or shape, but in later trials, a shape (e.g., cross) is rewarded regardless of color. Errors, latency to respond and perseveration on previous rules

(e.g., continuing to choose green stimuli rather than crosses), provide a measure of executive function.

### History

The WCST was designed by Harry Harlow, David Grant, and Esther Berg as part of the latter's Masters thesis in the mid-twentieth century (Berg 1948) at the University of Wisconsin. It was developed for use with humans based on Harlow's studies of discrimination learning in rhesus macaques with and without brain lesions (Eling et al. 2008). According to Eling et al. (2008), the WCST can be thought of as inspired by the early work on concept formation by Ach (1921) who developed a task by which meaningless words were arbitrarily associated with images that shared a common feature. With the WCST, several multidimensional stimuli are presented and the experimental subject has to identify the sorting rule. For example, two-dimensional shapes of different colors and numerosity can be presented. Once the subject learns the rule (select all objects of a particular color), the rule is shifted several times (select all sets of three) and the experimenter measures how quickly the subject can apply the new rule. A low number of perseverative errors, in which subjects continue to match based on a previously rewarded rule, indicate high executive control. The procedure is nonverbal and thus it is surprising that it has not been applied more often in comparative studies. To date, the paradigm has not been used in any nonprimate species, probably because relatively few other species have been trained to respond on computerized systems (although see Morton and Avanzo 2011 for a study of set shifting in sheep and Brown and Tait 2016 for a review of related work in rodents).

### Modern Applications

The WCST is often used in clinical settings with humans (Milner 1963), but it has also been used in studies of nonhuman primates – both to better understand their cognitive capacities (Bonté

et al. 2011) and to identify brain regions implicated in the cognitive processes underlying performance on the task (Kwok et al. 2019; Mansouri et al. 2006). Performance is extremely sensitive to damage to the prefrontal cortex (Demakis 2003; Milner 1963). The primary function of the WCST is to assess impairments in executive function as it tests the ability to adapt behavior to a rapidly changing decision rule (Eling et al. 2008). Performance depends on working memory and requires that selective attention is directed to a single attribute that is shared among objects (Mansouri and Tanaka 2002). In addition to selective attention, the WCST requires the capacity to switch response strategies flexibly, inhibiting previously rewarded responses (Bonté et al. 2011).

The WCST also tests conceptual thinking as it assesses whether the subject can abstract the conceptual rule that links the stimuli. For example, Mansouri and Tanaka (2002) used a computerized version of the WCST with just the two dimensions of shape and color to assess the capacity of two Japanese macaques to identify the relevant sensory dimension for matching. The correct dimension for matching shifted from color to shape across ten transitions. That the monkeys succeeded in applying the rule to other samples in the stimulus set led the authors to conclude that they represented sensory dimensions in working memory, and used these concepts to guide their responses in the task. The WCST has revealed stark differences between human and nonhuman subjects in inhibitory and conceptual abilities in some studies, and comparable performance in others (Bonté et al. 2011; Moore et al. 2005).

## Variants

Bonté et al. (2011) tested 24 Guinea baboons (a large sample for this type of study) with the WCST and extended the paradigm to test set-shifting with paired-relational stimuli as well as stimuli that varied on only a single dimension. In the relational version (R-WCST), subjects had to inhibit responding to absolute stimulus properties in order to attend to the relations between stimuli. Whereas all 24 baboons demonstrated shifting with the traditional single dimension task, only

12 of them succeeded with the relational task. It was also found that age negatively predicted success, suggesting an early decline in executive control processes, with an even more pronounced decline with more abstract tasks. However, in addition to demonstrating age-related decline in executive function, the study did provide evidence of relational processing in baboons – an ability that has sometimes been ascribed uniquely to humans.

A more commonly used variant of the WCST is the Cambridge Neuropsychological Automated Test Battery (CANTAB). In this task, subjects are trained to make a discrimination on the basis of one dimension of compound stimuli. Once criterion is reached, they are presented with either intradimensional discrimination shifts, in which new exemplars are presented with the same dimension controlling discrimination, or extradimensional shifts in which new exemplars are presented with the other dimension controlling discriminations (Dias et al. 1996). Shnitko et al. (2017) developed a variant of these tasks that allowed rhesus macaques to reach criteria on eight sets of discriminations within a single session. The discriminations progressed in difficulty, including four reversals. Unique to this study was the ability to test monkeys in their home enclosures, but also the fact that each session began with the easiest discrimination regardless of prior performance, equating the training history between subjects and allowing for long-term analysis of cognitive flexibility within individuals.

The paradigm is relevant to modern studies of behavioral flexibility (Berg 1948), which has become a popular topic in comparative psychology in recent years. Flexibility has been lauded as a domain general measure of “intelligence” or “cognitive complexity” in nonhuman species. The construct of behavioral flexibility is assumed to incorporate components of inhibition and innovation, whereas the WCST can be more properly considered a measure of cognitive flexibility involving inhibition and set-shifting (Brown and Tait 2016). Subjects are required to inhibit responses to irrelevant attributes, including those that have previously been relevant for predicting reward. In the behaviorist tradition of the times, later papers by Grant and colleagues eschewed

cognitive terminology and focused on stimulus-reward associations in explaining subjects' performance in the task (Eling et al. 2008). However, as can be seen in modern applications, the WCST has been used to reveal cognitive abilities such as working memory and conceptual representations in nonhuman primates and could readily be applied to the study of other nonhuman species and nonverbal children. It is still considered the definitive test of executive function and has been shown to reveal cognitive deficits both as a function of brain damage and normal aging (Bonté et al. 2011; Moore et al. 2005).

### WGTA

The Wisconsin General Test Apparatus (WGTA) is a laboratory device originally designed for studying two-choice discrimination learning by monkeys. The testing platform minimizes many of the risks of research with nonhuman primates such as being bitten, scratched, or exposed to

potentially infectious bodily substances. The WGTA also provides experimental control against cuing effects, positional biases, and other sources of confounding and error. In its most basic form, the apparatus is a simple tray used to present discriminative stimuli and to provide rewards to the animal being tested, together with visual barriers to minimize unwanted cues. Accordingly, the apparatus was described “not revolutionary in design” (Harlow and Bromer 1938, p. 434); nevertheless, the WGTA (and its modifications) has been an important methodological innovation for more than 80 years in the history of comparative psychology, helping to produce quantitative and qualitative changes in our understanding of animal learning and cognition, and indeed altering the ways that such questions were asked of these animals (Washburn et al. 1994).

The WGTA was first described in an article by Dr. Harry F. Harlow and Dr. John A. Bromer (1938), who indicated that “special acknowledgments for ideas utilized in the preparation of this apparatus are due Dr. Paul H. Settlage and Dr. Walter F. Grether” (p. 434). According to a footnote, the article was recommended for publication by B. F. Skinner. Harlow and Bromer described the construction, purpose, and use of the WGTA, which was initially developed and used at the Wisconsin Primate Laboratory (now the Harlow Center for Biological Psychology) at the University of Wisconsin-Madison. The original WGTA was comprised of two parts: a cage that created the environment in which rhesus monkeys could be safely tested, and the aforementioned stimulus tray, originally described as “an attachable panel-holder, which provides tracks for sliding-panels used in testing” (p. 434). These sliding panels had recessed wells into which reinforcers could be placed and then concealed by stimulus objects that were placed over each well. A researcher could retract the sliding panels and lower a screen so that stimuli could be positioned, and wells could be baited out of the test animal’s sight. Raising the screen allowed the stimulus trays to be extended toward the animal, which could then select from the stimulus array by reaching from the cage, displacing a stimulus object, and (if the correct object was selected)

retrieving the reward from the well. The experimenter could observe the animal’s choice, but a screen or one-way mirror prevented the animal from detecting visual cues by the experimenter (see also Davenport et al. 1970). Following a response, the sliding panels could be retracted and reset for the next trial. In this fashion, monkeys could be tested on a variety of psychological paradigms, including two-choice discrimination-learning, reversal testing, matching-to-sample (MTS), nonmatching-to-sample, delayed MTS or delayed responding, oddity, transposition, relative numerosness judgments, and many other assessments (for a review of much of this literature, see Schrier et al. 1965). Using this apparatus, Harlow (1949) collected the data for his classic “learning set” study that showed that rhesus monkeys “learn to learn,” and from which this oft-used illustration of a WGTA first appeared (Fig. 1):

Learning set, and the WGTA that gave rise to the phenomenon, has been described as the revolutionary keys that unlocked the field of animal learning from the associationist bonds of Hullian psychology (Rumbaugh 1997)

The WGTA had several features that made it attractive to researchers in the field of comparative psychology. In addition to the safety and experimental control discussed above, and the ability it provided to replicate and extend the work of a giant in the field like Harlow, the apparatus made it easy to standardize stimulus presentations, to quantify the animals’ responses, and to vary a large number of learning-relevant parameters such as whether or not the animal could see the baiting of the wells, the intertrial and retention intervals, the characteristics of the stimuli and the rewards, and so forth. The WGTA had one significant disadvantage that may have limited its growth in the field: in its original design it was a manual apparatus, with all components and phases requiring human intervention. However, semi-automated and automated variations on the WGTA were developed and reported in the literature (e.g., Davenport et al. 1970; Livesey et al. 1972; Wright et al. 1971), arguably extending to the computerized testing paradigm for primates that implemented the strengths of the manual

### Wisconsin General Test Apparatus,

**Fig. 1** Wisconsin general test apparatus. From Harlow (1949), p. 52

WGTA into a fully automated, game-like video task (Washburn et al. 1989). The apparatus was also modified for portability (e.g., Hunton and Hicks 1959; see also Whitham et al. 2018). Although originally developed for use with monkeys, the WGTA has been modified as needed for use with a wide array of organisms, including pigeons (e.g., Millar and Malott 1968), raccoons (Michels et al. 1960), cats (e.g., Warren 1980), dogs and wolves (Ebel and Werboff 1967; Frank et al. 1989), rabbits (Livesey 1965), prairie dogs (Cain and Carlson 1968), gerbils (Blass and Rollin 1969; King et al. 1968), rats (Valle 1971), chimpanzees (Rumbaugh et al. 1987), a variety of small primates (Pournelle and Rumbaugh 1965), and human children – with and without developmental disabilities (e.g., Graff and Green 2004; Levinson and Reese 1967; Orlando et al. 1960; Olson et al. 1966; Weisberg and Simmons 1966).

The heyday of the Wisconsin General Test Apparatus was during the 1960s and 1970s, but in subsequent decades the testing paradigms that are well suited to the WGTA have principally moved to computer-based technologies. Nevertheless, the literature shows several 100 WGTA-based publications in every decade since Harlow's (1949) landmark report, showing that there are

many designs for which the apparatus remains ideal, even for contemporary research.

## Synonyms

Drug withdrawal; Drug withdrawal syndrome;  
Substance withdrawal syndrome

## Definition

In a broad sense, withdrawal refers to the treatments, mechanisms, and behavioral effects after the removal of a biologically significant stimulus that an organism has experienced chronically. Such biologically significant stimuli may be drugs, high energetic food, and any eliciting stimuli or reinforcer (for “reinforcement withdrawal,” see “Extinction” entry). In a narrow sense, “withdrawal” is associated with the behavioral consequences of drug cessation and has been focused on the clinical aspects of such behaviors: abstinence symptoms. That is, it is used to define a syndrome in which aversive symptoms are experienced upon reduction or cessation of drug consumption, in an organism with a chronic experience with the drug. Diverse symptoms have been related to the abstinence of specific drugs, and in general, these are progressively relieved within days and weeks after abstinence, or when drug consumption is resumed (Hindocha et al. 2018; Schlienz et al. 2017). In this clinical perspective, withdrawal may include the following symptoms: impaired cognitive performance, such as response inhibition and delay discounting;

ffective symptoms, including irritability, anxiety, and depression; and physiological symptoms, such as restlessness, nausea, and headaches. (Hindocha et al. 2018).

Next, we review psychological theories that account for both the broad and narrow behavioral effects, while we focus on examples of drug withdrawal (rather than to focus on other reinforcers, like food, sex, etc.). Such theories have been developed in the field of animal learning and have been applied to explain and treat the abstinence symptom. We then review diverse behavioral manipulations and assessment of withdrawal behavior in animals.

## Psychological Models of Withdrawal

In psychology, withdrawal has been explained by at least two complementary theories: Solomon and Corbit's opponent-process model of emotion regulation (Solomon and Corbit 1974) and Siegel's compensatory model of drug tolerance (González et al. 2019; Siegel et al. 2000; Siegel 2016). Solomon and Corbit's model, based on a homeostatic theory of emotion regulation, would explain the effects of drug consumption: its tolerance, and withdrawal, as consequences of the dysregulation that drug intake provokes in an organism and its homeostatic reaction to it. For this model, an eliciting stimulus that breaks the homeostatic balance, in this case the drug intake, induces a biphasic state. Initially, a strong primary process is evoked and represents the unconditioned effects of the drug in the organism (an emotional response to the drug; e.g., pleasure, extasis). Then, as an unconditioned response to the primary process, the organism elicits a secondary, opposite, emotional process aimed to counteract the effect of the drug and to favor the return to a homeostatic state (an emotional response to the primary process; e.g., an aversive emotional state). When the organism lacks experience with the drug, this secondary process is originally slow to develop and weak, compared

with the primary process, and it is mainly evidenced when the stimulus is no longer present, as an affective postreaction (i.e., when the effects of the drug have ended the secondary process lingers briefly). After several exposures to the eliciting stimulus, the secondary process begins more simultaneously with the onset of the primary process, becomes stronger in intensity, and persists longer in time, which allows it to be more effective in counteracting the primary, unconditioned, effect of the drug in the organism. This more effective secondary process is then responsible for provoking a habituated response to the drug, a phenomenon known as drug tolerance, and an increased affective post-reaction when the effect of the drug ends (e.g., where this unbalance in homeostasis generates anxiety, a typical affective symptom of withdrawal) which is considered a strong withdrawal response. Thus, the model is well suited to explain the general effect of drug tolerance and its related withdrawal effect, but it misses a fundamental feature of these phenomena: their situational specificity.

Shepard Siegel's model (Siegel et al. 2000) gives a pivotal role to drug-related cues in the development and maintenance of drug tolerance and withdrawal, complementing the opposite-process model's explanation of these phenomena. For this model, the effects of drugs in the organism are considered unconditioned stimuli that automatically elicit unconditioned responses to compensate for the disturbance produced by the drug intake, which reduces or counteracts the experienced effect of the drug. As drug consumption occurs in specific situations, an association is established between the contextual stimuli in which consumption occurs (conditioned stimuli) and the effects of the drug in the organism (unconditioned stimulus; González et al. 2019; Siegel 2016). Then, given the association between drug-related cues and the effect of the drug, these cues come to elicit conditioned compensatory responses aimed at reducing the disturbance provoked by the drug in the organism, contributing to the development of drug tolerance, and explaining the situation specificity of this phenomenon. For this Pavlovian conditioning model of drug tolerance, withdrawal is the expression of conditioned

compensatory responses elicited by drug-related cues, when organisms are confronted with such cues in the absence of drug administration or after the cessation of its effects. Such responses appear as a preparatory state to counteract the homeostatic disruption caused by the drug, but in its absence are experienced as withdrawal symptoms (González et al. 2019; Siegel et al. 2000).

These theories and different clinical aspects of withdrawal have been studied using animal models, allowing not only the determination of the mechanisms and neurobiological substrate that underlie addiction and withdrawal but also to assess the impact of these phenomena on behavior.

## Behavioral Assessment of Withdrawal in Animal Models

In humans, general withdrawal symptoms can be assessed through tests such as the "Mood and Physical Symptoms Scale" (MPSS; Hindocha et al. 2018) and others, which typically assess physiological and anxiety symptoms that result from drug cessation. Also, different animal models are used to study the behavioral aspects of withdrawal. In general, withdrawal can be measured in any response system affected by a perturbation in homeostasis, and that is bidirectional from the baseline. In the specific case of nicotine, for instance, these models allow measuring different behaviors associated with withdrawal, such as affective signs (mostly anxiety-like behavior and reward-related measurements and somatic signs), locomotor activity, and hyperalgesia (Jackson et al. 2015).

In the case of alcohol withdrawal, after chronic alcohol administration in rats, the animals exhibited aversive withdrawal symptoms manifested as increased sensitivity to stress, depressive-like behaviors (e.g., assessed using a forced swim test), and higher anxiety levels, (e.g., assessed with an elevated plus-maze task and a marble-burying test; Li et al. 2019). In these animals, it was also determined that intracranial injection of glycine diminished these symptoms, and also decreased alcohol consumption upon re-exposure, suggesting that glycine receptors could be a

potential target to treat alcohol use disorders and withdrawal symptoms (Li et al. 2019).

From a conditioning perspective, Siegel suggests an association between tolerance and withdrawal symptoms, in which the presence of predrug cues associated with drug consumption elicit the conditioned compensatory responses that mediate tolerances but, when these cues are not followed by drug administration, these anticipatory cues elicit instead withdrawal symptoms. The evidence shows that subjects that self-administer a drug (through instrumental learning in rats) experience greater withdrawal symptoms in comparison to subjects receiving the drug passively (Siegel et al. 2000). In experienced drug users, a small dose is indicative of a subsequent larger dose. Evidence also shows that when this small dose is not followed by a large dose, it induces withdrawal symptoms (Siegel et al. 2000). This phenomenon was described by McDonald and Siegel (2004) using intra-drug conditioning. In this study, as morphine elicits hyperthermia, the authors used hypothermia as a morphine withdrawal symptom, given this is a conditional response to the drug effect. First, they conditioned rats using three experimental groups: (1) rats trained with saline solution, (2) rats trained with low doses of morphine (5 mg/kg), and (3) rats trained with high doses of morphine (50 g/kg). Then, during a test season, in which rats were injected with low doses of morphine, only the rats conditioned to high doses of morphine manifested hypothermia, while those conditioned with low doses of morphine or saline solution exhibited hyperthermia. From this study, the authors conclude that pharmacological cues can also play a pivotal role in Siegel's model, where modifications in drug dose (high to low) implied the evocation of conditional response in these animals, manifested as withdrawal symptoms (McDonald and Siegel 2004).

Conditioning learning tasks, such as contextual fear, have also been recently used to assess the impact of withdrawal on cognition. In this case, it was observed that the animals trained in a Pavlovian contextual fear task under nicotine withdrawal (that is, 12 h after the last nicotine administration, and in a time frame associated with withdrawal

somatic signs including tremors, gasps, eye blinks, teeth chattering, ptosis, and body spasms), exhibited cognitive and affective changes, associated to an increased fear response along with an anxiogenic effect, in comparison with animals trained under nicotinic influence (Robble et al. 2020).

## Conclusions

The study of the psychological processes underlying the acquisition of drug tolerance and its associated withdrawal severity and progression is relevant, given the functional impact associated with these phenomena, and its mechanisms, as they are implicated in the maintenance of homeostasis. In human animals, is also important for the assessment and elaboration of public health policies and therapeutic approaches to treat drug addictions. In this regard, the use of animal models is a relevant tool to assess this field, due that they allow us to study both the psychological predictions that underlie tolerance and withdrawal behaviors, as well to reveal the neurobiological substrate of these mechanisms.

## The Taxonomic Structure of the Living World

For decades in the past century, it was widely believed that all living entities on Earth could be neatly divided into two groups: the “prokaryotes (*pro* = before, *karyon* = nucleus) including the majority of single-celled microscopic organisms now known as bacteria and archaea and “eukaryotes” (*eu* = true, *karyon* = nucleus) that include single- and multi-celled organisms containing bona fide nucleus. This prokaryote/eukaryote dichotomy is still used by some textbooks and largely relied on a system that classified living entities on their visible or morphological characteristics.

It was Carl R. Woese in the 1960s and 1970s, a physicist-turned-microbiologist, of the “Urbana School” who wrote a new chapter in biology after spending years of work pioneering a new method to classify life. Woese was not impressed by the established methods of classifying organisms based on their shape or metabolic features. Because morphological characters, such as shape, color, and height, are often not comparable across distantly related organisms (e.g., bacteria and plants), Woese and colleagues spent years sequencing and comparing ribosomal RNA gene sequences across species. Their choice of using molecular characters (i.e., the smaller subunit ribosomal RNA) to (re)-classify life was the

stroke of genius since ribosome is central to life (mediates protein synthesis) and, to date, remains perhaps the best distinction between viruses and cellular organisms (Raoult and Forterre 2008). Moreover, ribosomal RNA is present in all cellular organisms and because of the centrality of its role in protein translation evolves much slower than most other genes, thus allowing comparisons across distantly related organisms. Ribosomal RNA is in fact commonly used today to recognize the taxonomic structure of microbial communities in environmental samples (e.g., “who is out there?”), an approach first pioneered by Norman Pace and coworkers (Pace et al. 1986).

Woese and coworkers discovered that cellular organisms formed three independent branches on the “tree of life” comprising eukarya, eubacteria (later bacteria), and archaeobacteria (later archaea) and directly challenged the established prokaryote/eukaryote paradigm (Woese and Fox 1977). Their proposal later became popular as the “three-domain classification” system of living organisms (Woese et al. 1990) since it led to the recognition of Archaea as a separate domain of life different from Bacteria and Eukarya.

Woese's discovery raised several interesting and controversial follow-up questions. Scientists began to wonder about the roles of Archaea in ecosystems and human health (DeLong 1992; Lurie-Weinberger and Gophna 2015), whether there were additional domains (e.g., viruses) that merited a place in the “tree of life” (Nasir and Caetano-Anollés 2015), how are the three domains related to each other (Forterre 2015), and if indeed the three-domain system fully negated the prokaryote/eukaryote dichotomy (Williams et al. 2013). Thanks to the continuous emergence of molecular sequence data on DNA, RNA, and proteins from hundreds and thousands of cellular organisms and viruses and the development of more sophisticated computational software to analyze large-scale datasets, the past 40 years have produced several fascinating studies directly attempting to answer these follow-up questions.

Archaea are now known to be abundant in ecosystems and also significant part of the human microbiota (i.e., the collection of archaeal,

bacterial, viral, and eukaryotic organisms that live on the human body) (Lurie-Weinberger and Gophna 2015). Despite several investigations, however, they are not known to cause human diseases (thankfully?) (Cavicchioli et al. 2003). Another interesting debate has been regarding the status of viruses as living or nonliving biological entities (Forterre 2016). Recent large-scale phylogenomic analyses focusing on protein structures rather than sequences have shown that viruses belong to the “realm” of life but likely originated multiple times in evolution (thus consider adding multiple domains to the tree?) (Nasir and Caetano-Anollés 2015). Another similarly controversial question has been regarding the evolutionary relationships among the three domains (Gouy et al. 2015). A shift toward combining and concatenating multiple proteins into a single phylogenetic analysis, as opposed to using single ribosomal RNA sequence, and implementation of sophisticated phylogenetic methods recently rejuvenated an old hypothesis where eukaryotes originated from within Archaea suggesting there were only two primary domains, Archaea and Bacteria (Williams et al. 2013). This hypothesis has been boosted by the recent discovery and recovery of near-complete genomes of several novel archaeal lineages from environmental data (Zaremba-Niedzwiedzka et al. 2017). These archaeal lineages encode many eukaryote-like proteins previously not detected or considered rare in Archaea suggesting that Archaea may be the mother of eukaryotes, not sisters, that transformed into modern eukaryotes once they engulfed the bacterial ancestor of modern mitochondria (i.e., the energy powerhouse in eukaryotic cells). However, several concerns regarding contamination during genome assembly from environmental data have recently been raised (Da Cunha et al. 2017), and hence the two-domain vs. three-domain question has now become one of the hottest debates in evolutionary biology. In other words, the Woesian “three-domain” tree of life after withstanding the test of time for four decades faces its sternest test today in the age where rapid genome sequencing directly from environmental samples has become the routine.

Despite the associated controversies, biology will always be thankful to the crucial contributions of Carl Woese. His efforts led to the wider recognition of Archaea, a vital component of our biosphere, and he pioneered the use of molecular characters in classifying life, an approach that has become the norm today. Carl Woese also inspired several young scientists (including AN), and his work triggered several exciting follow-up projects that continue to advance the growth of biology in the twenty-first century. Norman Pace perhaps best described Carl Woese, *Woese is to biology what Einstein is to physics*.

## Wolfgang Köhler (1887–1967)

Wolfgang Schönpflug  
Freie Universität Berlin, Berlin-Dahlem,  
Germany

Wolfgang Köhler was born into a Baltic German family in Reval (now Tallinn, Estonia) on January 21, 1887. He studied philosophy and natural sciences, especially physics, in Tübingen, Bonn, and Berlin, and graduated in 1909 from the Friedrich-Wilhelms-Universität in Berlin with a thesis supervised by the psychologist Carl Stumpf. He then worked as an assistant to Friedrich Schumann at the Psychological Institute in Frankfurt for 3 years, where he obtained a *venia legendi* (the teaching license required at German universities for appointment to a professorship). As a private lecturer (*Privatdozent*), without salary or tenure, he accepted the directorship in 1914 at the Station for Psychological and Physiological Research on Anthropoids in Tenerife, Spain of the Canary Islands. The Prussian Academy of Sciences

established the station in 1913 with funds from the Albert Samson Foundation, which were dedicated to researching the “natural and biological foundations of morality, for the individual as well as for society” (after Lück 1987, p. 171). In an enclosed space, Köhler (initially with Eugen Teuber who had established the station 1 year earlier) observed seven chimpanzees (from an original group of nine) that were purchased from Cameroon, then a German colony. After World War I, the Foundation was no longer able to finance the station. In 1919, the chimpanzees were sold to the Berlin Zoo, and Köhler returned to Germany.

At the University of Berlin, Köhler again obtained the license to teach as a lecturer in 1920. In 1921, he was appointed professor of experimental psychology and philosophy in Göttingen, and, back to Berlin in 1922, he became professor of philosophy and director of the Psychological Institute of the Friedrich-Wilhelms University. The Institute had just taken over two floors in a wing of the Berlin City Palace, which had been abandoned by the German Kaiser. At the time, it was one of the largest psychological institutes. Students, including an unusually high number of women for the time, came from many countries, and Köhler himself was very active in lecturing internationally. In the 1930s, he was an early critic of the spreading nationalist racial psychology and he took a public stand against the expulsion of Jewish scientists in 1933. When the National Socialists established a presence even at his own university, he resigned from his position in 1935 and left Germany.

At Swarthmore College in Pennsylvania (USA), Köhler continued his scientific work. From 1946, he was a research professor without teaching duties, and, from 1958, he was Professor Emeritus. After the war, his former University of Berlin became Humboldt University in East Berlin. The latter became the capital of a socialist German Democratic Republic after Germany’s division. The Free University of Berlin was founded in West Berlin, which belonged to the Federal Republic of Germany. Köhler was appointed honorary professor here in 1957 and made an Honorary Citizen of the Free University of Berlin in 1962.

In 1958/1959, Köhler was elected president of the American Psychological Association, and, shortly before his death in 1967, he was made an honorary president of the German Psychological Association (*Deutsche Gesellschaft für Psychologie*). He was, moreover, awarded eight honorary degrees from four US-American universities and colleges and from four European universities. Köhler died in Enfield, New Hampshire (USA), on June 11, 1967. In his memory, the Wolfgang Köhler Primate Research Center at the Max Planck Institute of Evolutionary Anthropology in Leipzig, Germany, carries his name (Asch 1968; Ebisch 2017; Jaeger 2003; Lück 1987; Schönplflug 2012, for a detailed biographical account, including memberships and honors, see Jaeger 1987).

In Berlin and Frankfurt, Köhler (1910, 1911, 1915a) conducted a series of investigations on hearing. To examine the physical and physiological characteristics of sound, he employed a method for registering the movements of the eardrum. He also studied the subjective aspects of acoustical sensations such as the brightness of sound in contrast to pitch. In Tenerife, Köhler (1915b) continued his studies on perception, this time with chicken, cats, dogs, and apes. He demonstrated that the principles of constancy (constancy of size, brightness, etc.) are as valid for animals as they are for humans.

Köhler is probably the best known for his studies on the mentality of apes. He conducted these studies in Tenerife in 1914, with several replications in early 1916 (Köhler 1917). He further made and reported on similar observations on problem solving concerning dogs and chickens and even a 1-year old girl. The investigator devised problem situations where goals could not be achieved in a direct way. In a standard experiment, hungry apes were offered bananas, but the direct path to the fruit was either blocked by a grate or out of reach (e.g., lying outside the cage or hanging from the ceiling). Other animals in a similar situation, like chickens, continued to take a direct path and failed to reach their goal if the way was blocked. In contrast, apes detected alternative routes. In one scenario, the apes could go to the opposite side of the grate by walking

around the wall in which the grate was installed. In other scenarios, they could pass the wall through openings or through doors that they had to open. The animals apparently took detours, even if they temporarily lost sight of their target.

The ability of apes to use tools was especially impressive. To extend the reach of their arm, they used poles. If a basket with fruit was hanging from the ceiling, the apes would climb on top of each other or jump on to a box. Sometimes they even stacked up to four boxes to get closer to the target. If a rope hoisted the basket, they would bite the rope or pull the rope to overturn the basket. These behaviors were all highly adaptive. For instance, if the investigator had filled the boxes with heavy stones or sand, the animals would empty the boxes in order to lift them. The apes attributed multiple functions to the same object. For instance, a pole could be used for climbing, jumping, and digging (e.g., for digging up edible roots); for retrieving items (as an extension of the arm); or as weapon (against an opponent). On the other hand, the same function could be attributed to different objects. Thus, instead of a solid pole, the apes used a wire, a piece of fabric, and even a bundle of straw to extend the reach of their arm. They, furthermore, not only used tools, but also made them. For instance, the apes inserted tubes into each other to increase their reach; remarkably, one ape even gnawed off a piece of a solid wood to fit it into the opening of a tube.

Yerkes (1916) made similar observations around this time, but Köhler (see 1921a, p. 194) only became aware of them after completing his own studies. Köhler (1921b) further published observations on the mentality of apes (regarding, among other things, their understanding of time) and on the role of sexuality in their social life.

The studies on problem-solving skills fueled academic debates and captivated the public. As far as psychological learning theory is concerned, Edward L. Thorndike (1898) had a marked behavioristic position, explaining problem solving as habit formation by trial and error. Depending on the success of certain actions, habits become gradually linked to situational stimuli. In contrast, Köhler advocated a cognitivist position, whereby animals operate on the basis of a mental

representation of a given situation. Indeed, their conscious imagination may even resemble that of humans. The mental representation also entails the ability to imagine alternative options, such as taking a detour or shortening the distance to a target by reaching out with a pole or stacking boxes. From this standpoint, problem solving is a process of cognitive structuring or insight; it is instantaneous rather than gradual or incremental.

For Köhler, insight (*Einsicht*) is a synonym for intelligence. Therefore, in attributing insight to apes he was also making an argument for the propinquity of animal and humans in general, and for the cognitive evolution of the species, in particular. Therefore, beyond the theory of learning, Köhler's research had an impact on biology and philosophy. His observations and explanations were enthusiastically welcomed and propagated by exponents of materialism and evolution theory against idealism and the clergy (e.g., Bölsche 1924).

*Gestalt* became a popular, yet equivocal concept in epistemology when Köhler and his colleagues in Berlin and Frankfurt demonstrated its potential for explaining perceptual phenomena such as stroboscopic movement and visual forms. In stroboscopic movement, the succession of discrete lights is subjectively transformed into a continuous flow of one single light, and in the perception of visual forms separate elements are organized to unitary patterns according to factors like proximity and similarity. As a result, closed, regular, and plain structures dominate. Examples include shapes like circles and rectangles in the stable visual field, and the continuity of events over time. Along with his friend Max Wertheimer (1925), Köhler (1929) interpreted such phenomena as evidence that there is an overall tendency toward coherence, simplicity, completeness, etc. or a "good *Gestalt*." He attributes the emergence of *Gestalten* to a dynamic, self-organizing process, which yields unified patterns or holistic structures. This approach has been applied to various areas of cognitive psychology, including acoustical and tactile perception, thinking, and memory (e.g., von Restorff 1933; Wertheimer 1945). It has further been extended to personality and group dynamics (e.g., Lewin 1951). The

Köhler-Wertheimer conception has gained currency worldwide as Gestalt psychology. A core assumption of the theory is that *Gestalt* formation is autonomous. Köhler (e.g., 1925) defended this hypothesis against the thesis that coherence is produced in a mental act of apprehension.

Contrary to the vitalist notion that holistic structures are a distinguishing feature of organic life, Köhler postulated Gestalt dynamics as universal processes in nature, which even operate in anorganic matter. He elaborates this view in *Die physischen Gestalten in Ruhe und im stationären Zustand* (Köhler 1920). At once deeply immersed in the world of physics and explicitly addressing philosophers and biologists, Köhler analyses stable equilibria and periodic oscillations. Focusing on fluids charged with ions and on electromagnetic fields, Köhler identifies forces driving toward economy, simplicity, and regularity and, accordingly, an equal distribution of energy. This process presupposes that there are relationships between elements constituting a field that transcends the sum of the elements' individual parts. Such field formation occurs autonomously, unless external barriers restrict it. Thus, "phenomenal *Gestalten* may well be understood . . . in conjunction with *Gestalten* from the physical province" (Köhler 1920, p. 172).

Köhler postulated the same inherent dynamics and holistic structures for the brain. He aims to present experimental evidence for this postulate in a study on figural after-effects, a phenomenon that Köhler discovered along with Hans Wallach. Here, lines are displaced and shapes are distorted when presented at the same location of the visual field where another line or figure has already been examined. This effect could be interpreted as due to satiation in an area of the visual cortex (Köhler and Wallach 1944). Later, Köhler designed electroencephalographic studies to demonstrate electrical fields generated in the brain that are analogous to visual patterns (Köhler and Held 1949). Thus, Köhler envisions *Gestalt* principles operating on the physical, physiological, and psychological level. Physical, physiological, and psychological phenomena exhibit structural concordances. The concordances should not be explained in terms of unidirectional causation from

the physical to the physiological and the psychological level. The concordances arise because they are based on the same natural principles. Related phenomena on these three levels are consequently called "isomorphic." Indeed, isomorphism has become the name of Köhler's theory of the structural correspondence between the physical, physiological, and psychological level.

As Köhler's studies on entropy and regulation show, he also addressed natural-philosophic and system-theoretical questions (Köhler 1927a, b). In *The Place of Value in a World of Facts*, Köhler (1938) presented his thinking on the current debates in epistemology and ethics. In contrast to theories that center on the judgment of value as related to human needs and interests, he posits value to be "a common trait of intrinsic requiredness" (Köhler 1938, p. 31). Value may be intellectual, moral, or esthetic. What is more, recognizing value is a matter of insight. The search for value is beyond phenomenology for it approaches the physical world. However, the approach to the organic and even the anorganic nature does not necessarily entail reducing psychology to physiology, or analysis to observation. In this sense, Köhler explicitly distances himself from both monism and positivism. (For a complete list of Köhler's publications, see Henle 1971; Jaeger 1987.)

## Wolfgang Köhler Primate Research Center

Tiffany A. Baker  
University of Southern Mississippi, Hattiesburg,  
MS, USA

## Synonyms

[Pongoland](#); [WKPRC](#); [Wolfgang Köhler Research Center](#)

## Definition

A project of the Max Planck Institute for Evolutionary Anthropology located at the Leipzig Zoo in Germany that focuses its research efforts on the study of the behavior and cognition of the four great ape species including chimpanzees, bonobos, gorillas, and orangutans (Wolfgang Köhler Primate Research Center 2018).

## Introduction

Named after Wolfgang Köhler, the Wolfgang Köhler Primate Research Center was first conceptualized in 1997 after the Max Planck Institute for Evolutionary Anthropology initiated focused efforts on the comparative observation of non-human primates. Shortly thereafter, construction of the Wolfgang Köhler Primate Research Center, otherwise known as Pongoland, began at Leipzig Zoo in Germany (Oberwemmer and Rasback 2001). Pongoland is one of six themed worlds located at Leipzig Zoo (Wolfgang Köhler Primate Research Center 2018). Upon the completion of construction, Pongoland first opened its doors to zoo visitors in 2001 (Zoo Leipzig 2018a). Four species of great apes currently reside at the Wolfgang Köhler Primate Research Center at Pongoland including chimpanzees (*Pan troglodytes*), bonobos (*Pan paniscus*), gorillas (*Gorilla gorilla*), and orangutans (*Pongo pygmaeus*). Researchers from around the world unite at the center to focus combined efforts from a variety of different backgrounds on the behavior and cognition of all four ape species. In addition, the center devotes specific efforts to the investigation of the “ontogeny of chimpanzee cognition” (Wolfgang Köhler Primate Research Center 2018) because chimpanzees are the closest living relative to human beings (Tomasello and Call 1997).

## Wolfgang Köhler

Wolfgang Köhler (1887–1967) was a German psychologist who was instrumental in laying the foundation of Gestalt Psychology, an area of

psychology that focuses on understanding perception not as individual parts but rather as an organized pattern. Köhler also completed pioneering work on great ape cognition (Köhler 2013). He is most often remembered for his work on insight with chimpanzees (Köhler 1959).

## Max Planck Institute for Evolutionary Anthropology

The Max Planck Institute for Evolutionary Anthropology’s main goal is to “unite scientists with various backgrounds (natural sciences and humanities) whose aim is to investigate the history of humankind from an interdisciplinary perspective with the help of comparative analyses of genes, cultures, cognitive abilities and social systems of past and present human populations as well as those of primates closely related to human beings” (Max Planck Institute 2018). As such, the Wolfgang Köhler Primate Research Center became a natural project of the Max Planck Institute for Evolutionary Anthropology (Wolfgang Köhler Primate Research Center 2018). In addition to the captive colony of apes located at the center, the Max Planck Institute for Evolutionary Anthropology also conducts primate research at various field sites across the world (Max Planck Institute 2018).

## Leipzig Zoo

Pongoland is one of six themed worlds at Leipzig Zoo. In fact, Leipzig Zoo is home to over 850 species and subspecies of animals. It operates as one of the most advanced zoos in the world (Zoo Leipzig 2018b). One of Leipzig Zoo’s primary goals is to aid in animal conservation. The zoo accomplishes this by educating visitors about issues in conservation as well as by modeling the breeding program around recommendations of the European Endangered Species Program. The Wolfgang Köhler Primate Research Center supports the zoo’s efforts with their specific primate breeding plan and, in addition, provides research on great ape captive management (Wolfgang Köhler Primate Research Center 2018).

### Directors and Research Coordinator

As of 2018, Josep Call, Ph.D., maintained position as codirector of the Wolfgang Köhler Primate Research Center since 1999. He is also credited as a cofounder. Call earned his Bachelors of Art in 1990 from the Autonomous University of Barcelona in Spain, and, in 1997, received his Doctorate of Philosophy in psychology from Emory University in Atlanta, Georgia. Since 1999, Call has served as a senior scientist at the Wolfgang Köhler Primate Research Center, and is currently a professor in evolutionary origins of mind within the School of Psychology and Neuroscience at the University of St Andrews (Call 2009).

Michael Tomasello is sitting codirector at the Wolfgang Köhler Primate Research Center. He has maintained this position since 2001. Tomasello received his Bachelors of Art from Duke University in 1972 and, in 1980, his Doctorate of Philosophy in psychology from the University of Georgia at Athens. He is currently an honorary professor at the University of Leipzig's Department of Psychology, as well as a professor of psychology within the Department of Psychology and Neuroscience at Duke University located in Durham, North Carolina (Tomasello 2017).

Daniel Hanus has served as the research coordinator at the Wolfgang Köhler Primate Research Center since 2009. He received a Doctorate of Philosophy at Humboldt University in Berlin (Hanus n.d.).

### Animals

Representing all four great ape species, 50 animals occupy the Wolfgang Köhler Primate Research Center. The apes are divided into five groups. Chimpanzees constitute two different groups, one group consisting of 19 chimpanzees, whereas the other group consists of six chimpanzees. The other three primate groups housed at the center include a group of 11 bonobos, a group of five gorillas, and a group of nine orangutans. All units are mixed sex and range in age from young to old (Wolfgang Köhler Primate Research Center 2018).

### Facilities

The Wolfgang Köhler Primate Research Center currently has an indoor and an outdoor facility

for each of the five primate groups (Wolfgang Köhler Primate Research Center 2018). The center is one of the largest and the most progressive nonhuman primate facilities in the world. Designed to mimic the natural habitat of the great apes, facilities replicate jungles and are equipped with irrigation systems that allow for an abundance of greenery as well as brooks and ponds (Jišová 2007). Furthermore, instead of traditional zoo caging, the outdoor enclosures are separated by watercourses complete with safety nets to protect the apes from the possibility of drowning (Wolfgang Köhler Primate Research Center 2018).

### Enrichment

The Wolfgang Köhler Primate Research Center offers 7000 m of rope (Wolfgang Köhler Primate Research Center 2018) as well as trees for climbing. Different foraging devices are also available. These devices encourage tool use for food access to mimic natural foraging behaviors. Furthermore, daily enrichment materials are provided that encourage activity and serve to prevent boredom (Wolfgang Köhler Primate Research Center 2018).

### Animal Keepers

Employed by the Leipzig Zoo, 14 zoo keepers provide daily animal care to the great apes at the Wolfgang Köhler Primate Research Center as well as the zoo. Zoo keepers are responsible for providing food three times a day, cleaning the facilities, providing enrichment at different times, in addition to hiding food throughout the enclosures (Wolfgang Köhler Primate Research Center 2018).

### Research

Research is observational in nature at the Wolfgang Köhler Primate Research Center. As such, scientists observe different apes as they interact with their surrounding environment including humans and other members of their groups. Furthermore, scientists observe apes engaging in various problem-solving tasks (Wolfgang Köhler Primate Research Center 2018).

Per the Wolfgang Köhler Primate Research Center's website (2018), research at the center is

categorized into two broad domains which include that of social cognition and physical cognition. Within the domain of social cognition, research is further divided into four areas including theory of mind, gestural communication, cooperation and prosociality, and social learning. Significant discoveries have been made in each of the areas of focus. For example, research at the Wolfgang Köhler Primate Research Center has supported the presence of key features of “theory of mind” in great ape species.

Pertaining to physical cognition, researchers investigate ways in which the great apes solve problems to gain insight about the underlying cognitive processes. Organized into three main areas, efforts regarding physical cognition are focused on three main areas which include spatial cognition, planning, and causal knowledge (Wolfgang Köhler Primate Research Center 2018).

## Conclusion

In summary, the Wolfgang Köhler Primate Research Center is a project of the Max Planck Institute for Evolutionary Anthropology housed at the Leipzig Zoo. Within the zoo, the center is located at Pongoland, one of six of Leipzig Zoo's themed worlds. Not only is the Wolfgang Köhler Primate Research Center one of the largest primate facilities in the world, it also utilizes progressive techniques to most naturally mimic the natural environment. Four species of great apes are housed at the center including chimpanzees, bonobos, gorillas, and orangutans. Researchers gather from around the world to study the social and physical cognition of these great apes. The center is currently co-director by Josep Call and Michael Tomasello.

## Woolly Mammoth

Joy Vincent  
Oakland University, Rochester, MI, USA

### Synonyms

*Mammuthus primigenius*

## Definition

The woolly mammoth is one of the most well-known extinct mammalian species, both because of its connection with the Ice Age as well as an extensive and pristine fossil record. As members of the Elephantidae family, their closest living relatives are Asian and African elephants. They are distinguishable from modern elephants due to their larger stature, hairy coat, and large curved tusks. Despite differences in climate, scientists have been able to make generalizations about the life history of woolly mammoths based on what is known about extant elephant species. Notably, it is believed that they had similar social structures and gestation periods. However, due to the harsh climate of their home ranges, woolly mammoths had stricter mating schedules to ensure births in the late spring as well as seasonal migrations through their territories to find food. Additionally, they evolved several unique morphological adaptations in response to their climate. These very adaptations that made them specialized for life in the tundra likely became their downfall as temperatures began to rise at the end of the ice age, causing dramatic changes to the landscape, forcing them to move more and more north in search of habitable environments. Eventually, the last of the mammoths persisted on islands in the Arctic Ocean, with the last of the woolly mammoths dying off on Wrangel Island, just north of Siberia, 3,700 years ago.

## Introduction

The woolly mammoth (*Mammuthus primigenius*) holds a prominent spot in modern mythos as a symbol of the most recent ice age. Their public recognition likely stems from their popularity in cave paintings as well as their pristine fossil record. To this day, the woolly mammoth is one of the most extensively studied extinct mammal species and was among the first species of the Pleistocene from which scientists have been able to recover DNA (Hofreiter and Lister 2006; Maschenko 2002). Given their preferred arctic climate, several mummified remains have been

found in Siberia, which have provided scientists with a plethora of information about their physiologies and diet (Guthrie 2001). Taken in conjunction with the mammoth's extensive fossil record, scientists have been able to formulate hypotheses about their life histories, drawing on parallels to modern-day elephants.

Similar in physiological appearance to extant elephant species, they are most recognized by their large, spiraled tusks and longer hair – both of which are adaptations to their lives in an arctic climate (Guthrie 2001). At the prime of their existence – approximately 300,000 years before present – their range spread over Eastern Europe, Northern Asia, and into North America (Nogues-Bravo et al. 2008). Their habitat, which has come to be known as the “mammoth steppe,” was characterized as cold, dry, open tundra predominantly covered by grasses and few trees. Toward the end of the ice age as the climate started to warm, the landscape began changing with temperate forests spreading more north (Hofreiter and Lister 2006). Eventually, Wrangel Island became the last known home of the woolly mammoth, with the last of their species dying off approximately 3,700 years ago (Vartanyan et al. 1993). Despite the time that has elapsed since the last woolly mammoth walked the earth, there is a wealth of knowledge about their life histories that scientists have been able to recreate.

## Evolutionary Origins

Due to their preferred environment of the mammoth steppe, and by virtue of its unforgiving temperatures, scientists have been gifted with one of the most complete and comprehensive records of morphological evolution in a large mammal (Lister and Sher 2001). The conditions of the steppe have preserved both the fossilized and mummified remains of mammoths, allowing scientists to effectively recreate their evolutionary origins. The Elephantidae family originated in Africa over six million years ago and has three extant species remaining: the Asian elephant (*Elephas maximus*), the African bush elephant (*Loxodonta africana*), and the African forest

elephant (*Loxodonta cyclotis*). There has been some debate over the taxonomy of the woolly mammoth within the family. Some scientists have argued that the woolly mammoth is most closely related to the African elephant based on similarities in the nuclear genome (Rohland et al. 2010). On the other hand, Hofreiter and Lister (2006) found that the mitochondrial DNA of the mammoth was more closely related to that of Asian elephants than African elephants, though the difference was not particularly big. They suggested that African and Asian elephants diverged around six million years ago, and then the Asian elephant and the mammoth lines diverged a half million years later.

While Hofreiter and Lister's (2006) taxonomic hypothesis may be correct, the earliest fossil records of the *mammuthus* genus have been traced to Africa, dating four to five million years ago. These individuals were believed to be morphologically similar to modern elephants, not yet having developed the hairy coat or exaggerated tusks. They entered Europe approximately three million ago (Hofreiter and Lister 2006). Over time, as they progressed more northward, they began to show morphological and behavioral adaptations to the harsher climates, feeding on mostly bushes and grasses and developing the longer hair, characteristic of the woolly mammoth (Hofreiter and Lister 2006).

The *mammuthus* genus has typically been split into three chronospecies, differentiated by their temporal existence. These were *M. meridionalis*, which lived in the early Pleistocene from 2.6 to 0.7 million years ago; *M. trogontherii*, which lived in the early middle Pleistocene from 0.7 to 0.5 million years ago; and the woolly mammoth, *M. primigenius*, which roamed in the late middle and late Pleistocene from 0.35 to 0.01 million years ago (Lister and Sher 2001). Additionally, a series of genetic studies revealed that the woolly mammoth chronospecies can be further subdivided into two clades. Some scientists suggested that these clades resulted from allopatric speciation, due to their geographic separation on either side of the Bering Strait (Gilbert et al. 2008; Maschenko 2002). Clade I was believed to have originated in North America and spread into

Eurasia and eventually went extinct in the Holocene. In contrast, Clade II was believed to have originated in Siberia and had a more limited geographic distribution, going extinct earlier than Clade I in the late Pleistocene.

## Life History of the Woolly Mammoth

Woolly mammoths are unique in that scientists can draw on knowledge about their extant relatives to fill in the blanks about their life histories that cannot be explained through fossil records. While life in the mammoth steppe during the ice age was certainly divergent from that of modern elephants that live in tropical-temperate regions, there are several parallels that can be drawn between Elephantidae family members. Moreover, researchers have been able to draw on observations of extant northern ungulates to recreate the life history of the woolly mammoth in its prime (Guthrie 2001).

Modern elephants exist in matriarchal family units, composed of related females and their juvenile offspring. Male elephants leave their family herd when they reach sexual maturity, venturing off on their own or forming bachelor herds (Pecnerova et al. 2017). Many scientists have presumed logical parallels between the social organization of extant elephant species and woolly mammoths (Hofreiter and Lister 2006; Maschenko 2002). Centralized fossil remains of woolly mammoths suggest that they had mass grave sites, similar to modern elephants. An analysis of a well-studied grave site in Sevsik showed that the composition of remains was not unlike that of modern elephants, which has lent credence to the belief that they had similar social structures (Maschenko 2002). This parallel between social structures has opened the door for additional assumptions to be made about other facets of their lives, such as mating and rearing of offspring.

It is believed that woolly mammoths had a similar gestation period to the 22 months of a modern elephants (Guthrie 2001). Unlike elephants, however, it is likely that they had a far smaller window of fertility each year. Woolly

mammoths faced incredibly harsh seasonal changes between winter and summer, necessitating a more condensed period of rut, which fell in early autumn (Maschenko 2002). Not only did this time frame allow for both sexes to amass substantial fat stores, but it also ensured an ideal birthing period of late spring (Guthrie 2001). The unfortunate consequence of female mammoths coming into estrus – their period of fertility – at almost the same time, was that confrontations between competing males were more numerous and intense than those of modern elephants. It is believed that the constrained rut times are partially to thank for the evolution of their characteristically large tusks, since this period of competition favored more dominant individuals with more exaggerated weaponry (Guthrie 2001).

Unlike modern-day male elephants that experience musth – periods of high androgen levels, increased sexual arousal, and increased intrasexual aggression – periodically throughout the year, male woolly mammoths experienced this only during the short period of rut when females were in estrus. This allowed them to form bachelor herds for the remaining 11 months of the year that were more permanent than those observed in extant elephants (Guthrie 2001). These bonds likely developed at an early age, as young males likely left their natal family herds around 13–15 years of age and formed or joined a bachelor herd. Scientists believe that these bonds were incredibly important for their survival in the harsh mammoth steppe, as solitary individuals were more likely to fall victim to natural traps, such as tar pits (Pecnerova et al. 2017).

There were many pitfalls that woolly mammoths had to face by virtue of the unforgiving landscape that they called home. The winter months were particularly challenging, as their normal sources of food were covered by snow and ice. This is why scientists postulate that calves of 3–5 years of age were weaned from their mother's milk in the springtime when the grasses began growing again (Guthrie 2001). This timing would provide the calves with the best chances to endure the removal of milk from their diet and coincided with when the mother's next calf would likely be born (Rountrey et al.

2007). To survive, mammoths had to consume 7–8% of their body weight each day in green vegetation (Maschenko 2002). Although they had a relatively diverse diet, they relied extensively on grasses. Stomach content analyses revealed that the types of plants consumed by mammoths, while lower in biomass than the plants commonly consumed by modern elephants, were notably high in nutrient and caloric content (Guthrie 2001; Kuzmin 2009). This efficient foraging behavior was crucial to their survival especially in the winter months.

Maschenko (2002) suggested that there were two distinct periods in the yearly cycle for the woolly mammoth that coincided with the summer and winter seasons. He suggested that during those periods, there were distinct differences in the types of food that they consumed, which varied by their seasonal territory. In the summer, grasses were more prevalent, making that the food of choice; however, in the winter, they were forced to feed on bushes, trees, and dry grass. Moreover, during the summer months, family groups likely resided in a relatively small area of their overall territory. As the productivity of food in this small area decreased when the growing season came to an end, families were forced to extend their ranges in search of more food. Due to the low levels of plant biomass, coupled with the mammoths' sizable caloric need, they had to traverse more of their territory in the winter months.

During the winter months, as food sources were depleted, mammoths had to continue moving in search of available resources. It was believed that, during the winter, they spent about 3 months traveling southward, and then returned to the north for the summer season. During this time, they likely traveled between 900 and 1,200 km away from their summer range, topping out at about 20 km per day (Maschenko 2002). Unlike traditional migrations wherein the goal is to reach a warmer climate, woolly mammoths were driven simply by the search for new food sources. During this period of migration, scientists believe they spent nearly 75% of their time foraging, rather than actively moving (Maschenko 2002).

## Morphological Adaptations

Existing climate data for the time when woolly mammoths roamed the earth indicates that the average ambient temperature ranged from  $-30.8^{\circ}\text{C}$  ( $-23.8^{\circ}\text{F}$ ) in the winter up to  $14.5^{\circ}\text{C}$  ( $58.1^{\circ}\text{F}$ ) in the summer, with an average precipitation of 240 mm (9.5 in) per year (Nogues-Bravo et al. 2008). Woolly mammoths evolved a collection of morphological adaptations to combat the cold harsh environment in which they lived. As outlined above, their large, curved tusks were advantageous in fighting other males for access to mates. They also served a purpose in foraging. These 80 kg tusks could be used to remove snow that was covering plant life during the winter months (Hofreiter and Lister 2006; Maschenko 2002). Some scientists have argued that the spiral design and curvature of the tusks made them more durable for snow and ice removal (Maschenko 2002). In addition to dental adaptations for effective foraging, there are a number of skeletal differences between woolly mammoths and modern elephants that have been attributed to differences in foraging patterns. Most notably, their necks were shorter, and they had high domed skulls and sloping backs (Lynch et al. 2015; Maschenko 2002).

The other prominent difference between the bone structure of woolly mammoths and their extant relatives is the cortex thickness of the bone. Cortex thickness correlates with the bone loading experienced by an individual, which is closely related to both the activity of the animal as well as the animal's weight at their heaviest point in the year (Guthrie 2001). Woolly mammoths have higher cortex thickness than extant elephants, supporting other observations that they carried more weight on them (Haynes 1991). More specifically, they had high levels of subcutaneous fat, which was crucial for their survival in the winter months (Maschenko 2002). This has been supported by studies of mummified mammoth remains that show significant fat reserves (Guthrie 2001). Moreover, Lynch et al. (2015) suggested that adaptations for insulin signaling and adipose development were crucial to mammoths' survival in the harsh winters.

Apart from their tusks, the other most notable feature that differentiates the woolly mammoth from other members of the Elephantidae family is their coat. They are often depicted as having a variety of coat colors, ranging from orange to black, but it is not known whether these variations were natural or if they can be attributed to alterations during the mumification process (Hofreiter and Lister 2006). The hairs of their coat were approximately four times thicker than similar hairs in other mammals. Many people often presume that their thicker and longer coat was an adaptation to the cold climate; however, autopsies of mummified remains revealed that this may not be the case. Mammoths did not have the subcutaneous muscles responsible for making the hairs stand up straight, which is the main mechanism by which animals can use their fur to protect from ambient temperatures. Shilo and colleagues (1983) suggested that mammoths may have relied more on their vascular system and the movement of blood to their peripheries to maintain their warmth rather than reliance on their coats. In this same vein, mummified remains have revealed that mammoths had particularly small external ears compared to extant elephants. This has been attributed to their need to conserve heat, compounded with the diminished need for enhanced long-distance communication given the relatively open landscape of the mammoth steppe (Guthrie 2001).

## Factors That Led to Their Extinction

It is clear that woolly mammoths were uniquely designed for life in a harsh and unforgiving climate, and many scientists have suggested that this specialization that served them well for thousands of years was what led to their eventual extinction (Kuzmin 2009). In their prime, woolly mammoths spanned large parts of Europe, Asia, and North America, but by about 12,000 years ago, they were essentially extinct throughout most of Europe, existing mostly in Siberia until about 9,700 years ago (Kuzmin 2009). By that time, they were functionally extinct on mainland Siberia, and were then found on only a few islands in

the Arctic Ocean. The most famous of which was Wrangel Island, which is widely believed to be the last known place where mammoths existed until their complete extinction 3,700 years ago (Hofreiter and Lister 2006; Kuzmin 2009). The current hypothesis about the downfall of the Wrangel Island mammoths was that they faced a genetic bottleneck effect and this reduction in diversity dealt the last blow (Palkopoulou et al. 2015).

Humans have been pointed to in the debate over what led to the extinction of the woolly mammoth. This is often because of the relationship between the species that is well documented in cave art from the time. While some believe hunting of mammoths by humans was the last straw, others have pointed out the statistical unlikelihood that hunting had a significant impact on their numbers, particularly when considered in the context of the end of the ice age. Interestingly, there is a geographic divide between scientists who stand by the hunting hypothesis and those that disagree; those from Europe tend to accept the hypothesis, while those from Siberia do not (reviewed in Kuzmin 2009). This divide may be due to differences in environmental stressors. Even toward the end of the ice age, Siberia was a harsher environment, and thus, it may have been in the interest of the people living there to coexist with the mammoths rather than to extensively hunt them (Kuzmin 2009). Mammoths were critically important to humans at the time, not necessarily as a food source, but as a supplier of different resources. Much like modern elephants, mammoths were important ecosystem engineers in creating pathways through the environment. Additionally, they were great sources of dung, which was often used as fuel for fires (Pitulko and Nikolskiy 2012).

Approximately 15,000 years ago, the climate started to warm, causing temperate forests to spread north into the previously uninhabitable regions that made up the mammoth steppe (Hofreiter and Lister 2006). This change in landscape drastically reduced the available grassland upon which the woolly mammoth relied. This process is known as extinction lag, which is an extinction of a species characterized by expansive

net reduction in habitable range over thousands of years (Lister and Stuart 2008). By the start of the Holocene 10,000 years ago, trees and shrubs were well on their way to becoming the predominant foliage in the mammoths' range, while grasses and dwarf shrubs were quickly losing their hold on the landscape. There is a general consensus that the extinction of the woolly mammoth was closely correlated with the decrease in the mammoth steppe as the earth began to warm following the ice age (Kuzmin 2009).

As the mammoth steppe became more and more fragmented by the encroaching temperate forests, populations of the woolly mammoths were forced to become more and more concentrated in the remaining territories (Maschenko 2002). The overpopulation of small areas likely led to dramatic reductions in the numbers of both mammoths and other large herbivores of the time. This ecological pattern has been observed in modern African elephant populations when they are driven into small territories. The rapid increase in population density causes a crisis in the plant community as consumption goes into overdrive, quickly rendering the environment barren and unsustainable (reviewed in Maschenko 2002).

It is evident that changing landscapes due to changes in the global climate struck a disastrous blow to the species. While the severity of the impact that human actions had on the mammoth population is debated, it is plausible that they may have added strain to an already crippled population (Nogues-Bravo et al. 2008). Regardless of what struck the final blow to the woolly mammoth, it is clear that their extinction was a complex process that happened over thousands of years.

## Conclusion

The woolly mammoth is one of the most well-known and well-studied extinct mammal species. Their pristine fossil record has allowed scientists to extensively study their evolution, life history, and eventual extinction. As a hallmark of the ice age, they exhibited several morphological and behavioral adaptations to life in the harsh climate

of the mammoth steppe. Despite some differences, there are a number of parallels that can be drawn between woolly mammoths and extant elephant species. This has allowed scientists to reasonably draw conclusions about their life histories. In the same way that conclusions can be drawn about the woolly mammoth from modern elephants, it may be possible to do the inverse, using what is known about the demise of the woolly mammoth to avoid the same fate befalling the extant members of the Elephantidae family.

Universidad Autónoma de Madrid, Madrid, Spain

## Definition

Working memory is a system of memory that stores a few pieces of information for a few seconds. However, unlike short-term memory, working memory is capable of operating and manipulating stored information.

## Introduction

The study of human memory, and in particular the study of working memory (WM), is not an easy

task. Most of the time, researchers have to infer how this process works through participants' behavior in experimental tasks or more recently through their brain activity. Usually, when a considerable amount of new experimental data about memory or any other mental process is available, researchers create models that attempt to explain the observed behavioral data. These models can then be used to generate new hypotheses, which can then be experimentally investigated.

One of the most influential models in early memory research was proposed by Atkinson and Shiffrin (1968). Also known as the multi-store model or the modal model, it assumes the existence of three systems of memory that are relatively independent: sensory memory (SM), short-term memory (STM), and long-term memory (LTM). According to this model, external information is detected by the sensory organs and transferred directly to SM. The information is stored in SM for just a few tenths of a second, but that information might be transferred to STM if attention is paid to it. STM is a limited storage that can keep a few items of information active for a few seconds. Although it depends on some factors, like the kind of information, the state of the participant, and the demands of the task, it is usually assumed that STM could store  $7 \pm 2$  items, which is referred to as Miller's law (Miller 1956). According to this model, only the information active in STM could be recalled consciously by participants. The third information storage unit, LTM, is defined as an unlimited store in which information could be kept indefinitely. This model proposes that through rehearsal or repetition, information could be transferred to LTM from STM. Finally, this model also assumes that the information stored in LTM could also be retrieved from STM for its recall.

The Atkinson and Shiffrin's model explained much of the data that were available when it was originally formulated; however, there is a data that the model cannot explain. For example, Shallice and Warrington (1970) described a patient with deficits in STM but with apparently intact LTM. According to Atkinson and Shiffrin's model, if the STM is damaged, the information could not be transferred to LTM because STM is the only access to LTM. Moreover, that model assumes

that only by repetition, can the information be transferred from STM to LTM. However, Craik and Lockhart (1972) showed that the depth of information processing is more important than the repetition of the information to transfer information to LTM. Nevertheless, Atkinson and Shiffrin's model was relevant in the psychology of memory because it assumes the existence of different memory systems; it explains how they interact with each other and highlights the importance that other processes like attention or repetition have within the memory.

Some experimental results suggested that, in some cases, memory is not only a mere information store in which information is collected and retrieved. In contrast, memory could also manipulate the information stored. We manipulate the information that we have in the memory, and as a result of this manipulation, new information is generated. For example, we can learn a list of numbers (e.g., 3–2–1–5–4) and repeat it after a few seconds. We can also add to these numbers and get to a result (e.g.,  $3 + 2 + 1 + 5 + 4 = 15$ ). It is assumed that the first task (to memorize and recover) is conducted by STM, and the second task (manipulation of the information) is performed by WM. Below the different approaches of WM will be discussed; for now it is enough to know that WM is a store of information of limited capacity that allow the manipulation of information unlike other systems of memory such as SM, STM, or LTM.

## Multicomponent Model of Working Memory

Although the term WM was first introduced by Miller et al. (1960), our understanding of it is primarily due to the contribution of Baddeley and Hitch (1974) who developed the multicomponent model (for a new version of multicomponent model, see Baddeley 2000). Whereas Atkinson and Shiffrin's model hypothesizes the existence of a single short-term storage, where all kinds of information are stored, the model proposed by Baddeley and Hitch (1974) assumes that the information is collected in independent short-term storages according to if the information is

visual or verbal (or episodic in the new version of the model proposed by Baddeley 2000). According to that, Baddeley and Hitch (1974) proposed the existence of two components that store the information in WM: the phonological loop and the visuospatial sketchpad. Also, these authors proposed that a third component manipulates the information stored in phonological loop and in visuospatial sketchpad: the central executive.

The phonological loop maintains active verbal information through two subsystems: a short-term storage and an articulatory rehearsal. The short-term storage keeps verbal information active for just a few seconds, whereas the articulatory rehearsal repeats the information stored in short-term storage (like an internal speech) to maintain it as active. Some experimental effects support the existence of the phonological loop. For example, the phonological similarity effect (Conrad and Hull 1964) shows that if participants have to learn a list, which contains items that are phonologically similar (e.g., cat, tap, lap, rap), the recovery accuracy will be lower than if the items are phonologically different (e.g., two, tip, pot, lip). It is assumed that the similarity between items makes the articulatory rehearsal more difficult, which will lead to the recovery disruption. Also, if participants repeat an irrelevant word (e.g., the, the, the, the) while they are memorizing a list of items, later retrieval of the list will be less effective (Vallar and Baddeley 1984). According to Baddeley and Hitch's model, this activity, repeating an irrelevant word, will suppress the articulatory rehearsal, and therefore, the recovery accuracy will decrease.

In contrast, visuospatial sketchpad stores visual and spatial information. For example, remembering how many doors there are in the house that we lived in 10 years ago is a task that requires a visuospatial sketchpad. Like phonological loop, that component of WM is limited in capacity; it's assumed that it could operate with three or four objects at the same time. For this reason it can be disrupted by requiring participants to tap repeatedly a specified pattern of keys or locations, a procedure that impairs the use of visuospatial imagery (see Baddeley and Lieberman 1980). Logie (1995) proposed a

structure of visuospatial sketchpad that, like phonological loop, is formed by a passive storage and a rehearsal mechanism. The first would keep the information active, and the second would be a repetition of a mental scanning of the visual representation.

Whereas the function of the phonological loop and the visuospatial sketchpad is only the mere storage of the information, the central executive (the third component of the multicomponent model) supervises and manipulates the information that is collected in these two interfaces of working memory. In other words, according to this model, the central executive adds, deletes, and reorders information stored in the phonological loop and in the visuospatial sketchpad (and in the episodic buffer according to the revised multicomponent model proposed by Baddeley 2000), selecting the significant information that ultimately guides behavior, recovering information from LTM, and solving which information should be stored in LTM and which information should be discarded. Some researchers suggest that the central executive is also involved in cognitive functions like to process sensory information and store information in LTM and retrieve it (Gluck et al. 2009), setting goals and plans (Linnenbrink et al. 1999), task switching (Rouder et al. 2011), or stimulus selection and response inhibition (Kiyonaga and Egner 2014).

Although the multicomponent model predicted and explained a considerable amount of data found until the 1970s, it was unable to explain some effects like the resistance in serial recall to articulatory suppression or the improvement in the recall when items are integrated in some way (e.g., when they rhymes) instead of when they are unrelated, among others. Aiming to solve some of these limitations, Baddeley (2000) proposed a fourth component for the model that was not included in the original version of Baddeley and Hitch's (1974) model: the episodic buffer. This component is a multidimensional storage that keeps visual, spatial, and verbal information, combining it in chunks or episodes and maintaining it temporarily. According to Baddeley (2000), information is transferred to the episodic buffer not only from the phonological

loop and from the visuospatial sketchpad but also from LTM. As with the other two storage components of the model (the phonological loop and the visuospatial sketchpad), the episodic buffer is also controlled by the central executive. Also, Baddeley (2000) argued that the episodic buffer seems to play an important role in consciousness and awareness and that it contributes to the online maintenance of integrated memory traces. The revised multicomponent model proposed by Baddeley not only differs from the original model (Baddeley and Hitch 1974) by the presence of episodic buffer, but it also assumes the existence of a connection between the phonological loop and LTM. However, although the major evidence for this modification comes from the verbal domain, it is probable that the equivalent visuospatial linking to LTM also exists (Baddeley 2001).

## What Is Working Memory?

It is important to note that the definition of WM is not unanimous across authors. In contrast to other memory terms (like, e.g., LTM which most authors agree upon), WM is defined differently depending on the author and the consulted text. For example, in some texts WM and STM are used synonymously. This is the case for the Atkinson and Shiffrin's model (1968) which makes no distinction between these two memory systems. Other authors have used WM to explain the maintenance of information across some trials conducted in the same day (Olton 1979). According to the evidence found in the studies conducted in the last decades, these two definitions of WM have been rejected. Nowadays, most authors define WM as a memory system that stores a few pieces of information for a few seconds but that it differs from STM in that WM manipulates the information, whereas STM is only a storage component with no modification of the information. This vision of WM is the one that has received the most theoretical and experimental support.

However, it's unclear whether WM should replace STM or if these two systems of memory

may cohabitate and operate independently. In situations where there has no manipulation of information, both systems, WM and STM, are experimentally undifferentiable. According to that, instead of assuming the existence of both, WM and STM, it could be reasonable, and more parsimonious, to assume that there are no two systems of memory but just only WM. According to that there are two different kinds of tasks: tasks in which the WM operates with information and tasks in which WM does not manipulate any information. This idea, that makes STM useless, is supported by the Baddeley and Hitch's model assuming that tasks in which it is necessary to operate with information require the central executive to be active; in contrast, when no operation with the information is required and it needed just the storage and retrieval of information, the central executive will be deactivated.

Other authors consider WM not as a memory system like STM or LTM but rather as a mental process or a set of different processes. Moreover, they acknowledge that, like an independent cognitive system, WM allows us to handle information that is being processed (e.g., Miyake and Shah 1999). This is the newest approach to the study of WM. Unfortunately, there are not yet formal studies that have confirmed whether the nature of WM is a comparable memory system to STM or LTM or an independent process (for other definitions of WM, see Cowan 2008).

Finally, Ericsson and Kintsch (1995) proposed that WM could also operate within LTM, and they introduced the concept of *long-term working memory*. These authors suggested the existence of structures of information in LTM that provide participants the skills needed to perform specific tasks. When participants conduct a task, they retrieve the structures of information involved in it from LTM to WM. In WM these structures could change with practice becoming more suitable to this task. After, they are stored again in LTM. That process explains how participants to improve their execution in specific task throw practice. This idea account for the apparent efficiency of WM and the capacity of information processing that experts have in their specific areas. For example, professional chess players

could analyze their game much faster and more intensely than amateur players can.

## Working Memory Capacity

In contrast to other memory systems such as SM or LTM, WM has a limited capacity. Although WM span depends on variables like the age of participants, the task, and the materials used to measure it, among others, it has been proposed that, like STM, WM can handle  $7 \pm 2$  items (Miller 1956). However, some authors argue that WM operates with chunks of items instead of isolated items. For example, Cowan (2001) proposed that WM operates with a maximum of four chunks of items. The limitations of WM capacity and the WM span variability among people have led to some authors to hypothesize that WM is related to other aspects of cognition like reading (Swanson 2006), language (Archibald and Gathercole 2006), or mathematical skills (Passolunghi 2006). This idea suggests that WM span is a good predictor of a person's performance in other cognitive tasks. For example, in a seminal work, Daneman and Carpenter (1980) showed that WM capacity correlated with text comprehension. Some authors have suggested that improving WM capacity through training would also improve other aspects of cognition (e.g., Shipstead et al. 2010). However, a recent meta-analysis conducted by Melby-Lervag et al. (2016) suggests that it is still uncertain whether WM training is directly linked to improving cognition skills.

## Where Is Working Memory in the Brain?

With advances in neuroimaging techniques, recent research has attempted to identify the neuroanatomic correlates of WM. In particular, most of the authors have investigated which brain areas are related, or controlled, to the different components of the multicomponent model. For example, Paulesu et al. (1993) found that the area between the parietal and temporal lobes in the left hemisphere seems to be responsible for phonological

storage and that Broca's area is responsible for subvocal rehearsal. In the other hand, Smith et al. (1996) found that in visual tasks the right hemisphere was more active than the left. Furthermore, the frontal lobes, especially the activation of the prefrontal cortex, seem to be important for WM. For instance, Owen et al. (1996) found that the dorsolateral prefrontal cortex is used in tasks where the central executive is related. The left prefrontal ventrolateral cortex is correlated with the phonological loop, and it is divided into two areas: anterior, that handles semantic information, and posterior, for phonological information. In contrast, the right prefrontal ventrolateral cortex has been paired with a visuospatial sketchpad. The only component of WM that seems not to be controlled by frontal brain areas is the episodic buffer that seems to be controlled by left anterior hippocampus, in medial temporal lobe.

To sum up, it seems that most of WM functions are controlled by frontal brain areas, especially by prefrontal cortex. While left prefrontal cortex is associated with verbal WM, the right prefrontal cortex is responsible of visuospatial WM. Finally, dorsolateral prefrontal cortex controls the central executive and left anterior hippocampus, the episodic buffer.

## World Wildlife Fund (WWF)

Penthai Siriwat<sup>1</sup> and Sonia Tiedt<sup>2</sup>

<sup>1</sup>Oxford Brookes University, Oxford, UK

<sup>2</sup>Imperial College London, School of Public Health and Grantham Institute, London, UK

### Introduction

The World Wide Fund for Nature (WWF) is a charitable trust working in environmentalism, conservation, and ecology. The organization's mission statement is to conserve nature, to reduce the most pressing threats to the diversity of life on Earth, and to create a sustainable future where humans live in harmony with nature. It was established on April 29, 1961, by Prince Bernhard of Lippe-Biesterfeld; Prince Philip, Duke of Edinburgh; Julian Huxley; Max Nicholson; Peter Scott; Guy Mountfort; and Godfrey A. Rockefeller. The organization was originally established as World Wildlife Fund before changing its name in 1986. World Wildlife Fund is still the organizations' operational name in the United States and Canada. The first WWF office opened on September 11, 1961, in Morges, Switzerland. The current headquarters is in Gland, Vaud, Switzerland.

In order to achieve its mission statement, WWF formulated initiatives which address priority areas and species in need of research and conservation. These initiatives are based on six major goals and cover three main drivers of environmental problems. The six major goals include forests, oceans, wildlife, food, climate and energy, and freshwater, while the main drivers of environmental problems have been identified as markets, finance, and governance. The organization uses multidisciplinary research to form cutting-edge conservation tools and methods, increase connectivity in natural and social systems, and tackle

emerging threats imposed on our natural systems. The initiatives are strategically implemented through advocacy, policy reformation, and research conducted by a large network of researchers, partners, stakeholders in businesses, academia in partnership, and civil society which extends from local to global scales.

### History

The intended purpose in establishing WWF was to act as a funding institution for existing conservation groups. At the time, groups such as the International Union for Conservation of Nature and Natural Resources (IUCN) and the Conservation Foundation were carrying out conservation projects throughout the world. The idea of establishment was borne from the vision of Victor Stolan, Sir Julian Huxley, Sir Peter Scott, and E.M. Nicholson. Although each person came from diverse fields, together, combined decades of experiences documented in a pledge called the "Morges Manifesto" (WWF 1961). This main document elaborated the fund's commitment to assisting conservation causes.

Within its first year of establishment, the organization had supported working projects on the red wolf in the United States, the Tule goose in Canada, the Hawaiian sea bird, and the giant grebe of Guatemala. It then expanded its projects around the world, in Africa, Latin America, and Asia. In 1962, WWF gathered funds to establish the Charles Darwin Foundation Research Station in the Galapagos Islands. By 1975, WWF expanded its organization's scope to not only focus on species-related projects but also to carry out initiatives which also protected habitats through actively supporting the establishments national parks and nature reserves around the world.

The Conservation Foundation, an institution based on conservation policy, was also a vital partner which supported the formation of WWF. The Conservation Foundation was founded in 1948 by Fairfield Osborn as an affiliate organization to the New York Zoological Society (known today as Wildlife Conservation Society), with its primary goal to protect the world's natural

resources. The Conservation Foundation was formed of an advisory council of leading scientists including Charles Sutherland Elton, G. Evelyn Hutchinson, Aldo Leopold, Carl Sauer, and Paul Sears (Peahike 2013). The Conservation Foundation highlighted many of the issues faced in the twenty-first century, for instance, in 1963, the Conservation Foundation held a conference which published findings warning against anthropogenic global warming. In 1985, the Conservation Foundation became an affiliate of WWF, where it operated with the same staff but under a separate legal entity. Subsequently in 1990, the Conservation Foundation merged into WWF.

As the organization expanded, WWF set up offices and operations around the world. As the network and resources increased, the operations expanded into new areas of research, such as the preservation of biological diversity, sustainable use of natural resources, and reduction of pollution and climate change. In the 1980s, the organization strategized its projects and activities further and, in 1990, revised its mission statement three-fold. In the new updated mission statement, the organization aims to stop the degradation of the planet's natural environment and to build a future in which humans live in harmony with nature, by conserving the world's biological diversity, by ensuring that the use of renewable natural resources is sustainable, and by promoting the reduction of pollution and wasteful consumption. WWF obtained general consultative status from UNESCO in 1996.

The iconic giant panda was designed by Sir Peter Scott after a panda named Chi Chi which had been sent from Beijing Zoo to London Zoo in 1958. At the time, Chi Chi was famous for being the only panda residing the western region. Although the logo had gone through changes and redesigns over time, it is undeniably one of the most recognizable symbols of conservation and of the organization.

## Current Projects in the Twenty-First Century

The WWF is the world's largest conservation organization, with over five million supporters

worldwide and works in more than 100 countries and on 1300 projects (WWF 2019). The organization income is earned mostly from individual memberships and donations (35%) followed by in-kind and others (26%) and government grants (14%) (WWF-US 2018). In 2018, 84% of spending was directed to worldwide conservation (WWF-US 2018).

WWF's mission specifically focuses on restoring populations of 26 species (species or groups of species) which have been identified as vital to their ecosystems and to people, such as elephants, tunas, whales, dolphin, and porpoises. Furthermore, in a first of its kind worldwide biodiversity analysis, WWF scientists and experts identified ecoregions which represent biologically outstanding and unique ecosystems of terrestrial, freshwater, and marine habitats. In 2018, WWF identified 1480 ecoregions based on complex patterns of the natural ecosystems using factors like climate, geology, and the evolutionary history of the planet.

In addressing environmental problems of biodiversity loss and unsustainable use of natural resource, including finance and business practices as well as consumption choices, WWF launched multiple public campaigns to influence decision-makers, inform on policy changes, and conduct behavioral change campaigns to encourage people to live in a more environmentally friendly manner. WWF encourages people to be actively involved and donate funds to protect the environment.

Science is a large vital component of WWF's conservation work. The organization elaborates that the role of scientists is vital in developing innovative approaches to apply the best available information. Notable global campaigns include Debt-for-Nature Swap, Earth Hour, and Marine Stewardship Council. Debt-for-Nature Swap, for example, was implemented in 1987 in Ecuador. The project facilitated in buying of a countries' foreign debt at a discount, in order to convert the funds to local currency and using the money earned to finance conservation efforts. The Earth Hour is an example of a global movement carried out globally to raise awareness for energy consumption and effects on the environment. Furthermore, the WWF collaborates with local

populations, governments, and nongovernmental organizations to implement their initiatives. WWF also formed partnerships with global organizations such as the United Nations, the World Bank, and the European Union.

## Research Areas

WWF's conservation strategy is focused on six major goals. Food is one of the six key areas. The organization aims to fund projects which help to double net food availability while freezing its ecological footprint in a three-way approach: firstly, increasing efficiency and sustainability of food production addressing how food is grown and farmed; secondly, evaluating consumption and encouraging sustainable diets; and thirdly, zeroing in on food waste by ensuring that food is eaten and not wasted. By establishing a sustainable food system, food security can be safeguarded.

For climate, WWF aims to create a climate-resilient and zero-carbon world powered by renewable energy. In order to achieve a low-carbon future, WWF works together with finance institutions to produce attainable climate solutions, use alternative fossil fuels, disperse clean energy technologies, and restore forests. Furthermore, the organization aims to work alongside and assist businesses in order to achieve goals in cutting down carbon emissions.

Freshwater is one of the world's most shared vital resources. As a result, WWF has established a goal to increase freshwater security for people and nature through protecting fresh bodies of water and keeping rivers free flowing. Wetland restoration and protecting vital organisms living within the habitats such as river dolphins and sturgeons are also vital components of the goal. The Freshwater Report produces a summary of conservation projects carried out in over 50 countries. Water stewardship and collective responsibility for shared water resources among businesses and local stakeholders are essential in management of freshwater ecosystems.

One of the main areas of work WWF is known for since its establishment is the projects involving

wildlife. The goal to protect the worlds' most important species still remains today. In ecosystems that range from the poles to the tropics, WWF strives to preserve vital habitats by addressing protected area management. Legal and illegal wildlife trade and unsustainable wildlife consumption are also key issues threatening wildlife in the twenty-first century which are addressed. WWF works directly through related agencies and organizations to strengthen regulations, enhance monitoring tools, and provide support to law enforcement. On the other hand, in recognizing the importance of market and consumer behavior which drive demand for wildlife products, WWF also works in multiple awareness programs aiming to change consumer behavior and cultural perceptions.

Forests are also one of the six goals of WWF. The organization aims to address issues of deforestation, climate change, and forest transformation. Challenges in the forest sector are tackled using cutting-edge science in collaboration with stakeholders. WWF aims to protect the world's most important forests by increasing protected areas, improving forests under management, stopping illegal unregulated deforestation, and restoring forest landscape and connectivity.

The final goal of study by WWF is related to oceans and marine ecosystems. The organization aims to safeguard healthy marine ecosystems through management of reef mangroves, improving coastal areas, reducing pollution, and supporting sustainable fisheries. Plastic pollution in the ocean is a big concern addressed on a global scale. Working closely with stakeholders ranging from fishing communities, businesses, and governments can lead reduce the number of damaging activities imposed on marine environments. Restoring coastal environments such as coral reefs and mangroves is also a critical component in achieving the goals.

## Reports

Since 1998, WWF has produced the "Living Planet Report." It is a science-based assessment report released every 2 years based on the Living Planet Index and ecological footprint calculation.

The Living Planet Index measures trends based on data from populations of mammals, birds, reptiles, amphibians, and fish species across the world. The importance of this report is to review impact of human activity on the planet using science-based approach and analysis. Each report summarizes findings and offers suggestions in review of current efforts in achieving goals within environmental treaties and agreements made, such as the Convention on Biological Diversity, the Paris Climate Agreement, and the Sustainable Development Goals (WWF 2018). Latest trends show a decline of 58% of species between 1970 and 2012 (WWF 2018).

A key outcome of publishing reports is to raise awareness and provide information for policy- and decision-makers. WWF offices which operate globally aim to run alongside national councils, acting as support advisory groups. WWF works closely with national and international lawmakers to adopt, enforce, strengthen, and/or change policies or laws, supported by ground findings and scientific process and tools and methods. The organization addresses conservation issues in a multifaceted approach, working with every sector, whether it is to help educate and influence

people into making sustainable choices, or making businesses have accountability in the impact on natural resources use, or to push and ensure that governments commit to international initiatives to protect biodiversity and natural resources.

## Xenophilia

Jennifer Colbourne  
York University, Toronto, ON, Canada

### Synonyms

[Friendliness](#); [Openness](#); [Prosociality](#); [Tolerance](#)

### Definition

Attraction to and/or positive behavior toward strangers.

### Introduction

Xenophilia has only rarely been documented in nature. Because strangers often represent a threat to one's resources, territory, and mating success, there is often little evolutionary payoff for acting prosocially toward unknown individuals, and potentially great costs for doing so (Temeles 1994; Wilson 1975). However, there are some circumstances where natural selection has favored positive interactions with strangers.

## Mating

As a mechanism to avoid inbreeding in social living animals, young males or females may disperse to a new social group (Clutton-Brock 1989). Although the introduction of a stranger to a group can result in aggression and tension (Fragaszy et al. 1994), it is not unusual for opposite-sex individuals to be attracted to the newcomer, and in some cases may even protect them from attacks from other members of the group (Wade 1976). Even species that show highly xenophobic responses may show lower rejection of opposite-sex strangers due to the reproductive opportunity they represent (Spinks et al. 1998), especially during breeding season (Bernstein and Gordon 1974).

## Genetic Relatives

Hamilton (1964) predicted that animals should be prosocial and cooperative with strangers with whom they share genes. This is because helping kin to survive and reproduce increases one's indirect fitness, as the genes that are shared with the relative will have a higher probability of being passed on. However, kin selection requires the

ability to recognize genetic relatives. In some species, only conspecifics with whom individuals live with are treated as kin (such as nestmates), but other species are able to recognize unfamiliar individuals as genetic kin through scent, visual characteristics (e.g., phenotype matching), or other cues (Hepper 1986).

## Domestication

It has been argued that the main components necessary for domestication are increased tolerance and reduced aggression (Hare et al. 2012). A prime example is that of domestic dogs (*Canis familiaris*) which often enjoy socializing and playing with unfamiliar dogs, as exemplified by the popularity of public dog parks (Shyan et al. 2003). This behavior contrasts with that of wolves (*Canis lupus*), which are known to fight neighbors and engage in lethal raiding (Mech 1994). This type of xenophilic behavior shows remarkable individual differences, and has been captured in dogs by the personality trait of “sociability” (Svartberg and Forkman 2002) or “amicability” (Ley et al. 2008).

In an ongoing experimental project begun in 1959 by the geneticist D. K. Belyaev and continued by his assistant L. Trut, foxes (*Vulpes vulpes*) were selectively bred according to their aggressive response to humans. Foxes that were selected for tolerance began to show increasingly “dog-like” traits, including increased sexual activity, depigmentation, floppy ears, and curly tails (Trut et al. 2009). Thus, xenophilia may not only be a consequence of domestication, but the driving force behind it.

The only primate aside from humans known to routinely engage in xenophilic behavior is the bonobo (*Pan paniscus*), a great ape closely related to the chimpanzee. Hare et al. (2012) have made the case that the bonobo serves as an example of “self-domestication,” as bonobos share many traits in common with domesticated animals, such as a juvenilized appearance, depigmentation, and more frequent reproduction, in addition to reduced aggressiveness. Bonobos are known to play and copulate with members of strange groups, and although they also can engage

in hostile displays, physical contact is rare and lethality unknown. Several studies have demonstrated a preference for strangers over groupmates in bonobos, even at personal cost (Hare and Kwetuenda 2010; Tan et al. 2017). According to the first impression hypothesis, bonobos may favor strangers because they have the potential to become new long-term allies (Tan et al. 2017).

## Unicoloniality

Invasive introduced Argentinian ants (*Linepithema humile*) in Europe and North America appear to have lost their ability to recognize non-nestmates, and thus tolerate strange ants that they used to display xenophobic aggression toward. Starks (2003) has suggested that this tolerance developed because their new environments were so resource rich that aggression toward strangers became too costly and consequently selected against. The result has been the creation of vast “supercolonies,” which have been known to range over hundreds to thousands of kilometers. However, whether this type of unicoloniality can truly be said to be xenophilia is debatable, especially as members of supercolonies are also still aggressive against members of other supercolonies.

## Conclusion

The rarity of xenophilia makes it a phenomenon that has been little studied. However, it is clearly possible for xenophilia to develop under unusual selective pressures (introduction to a novel environment, domestication) or in certain circumstances where the benefits outweigh the costs (reproductive opportunities, helping kin). The genetic, physiological, and behavioral underpinnings of xenophilia remain to be examined in more detail.

## Xenophobia

Jennifer Colbourne

York University, Toronto, ON, Canada

## Synonyms

Antipathy; Intolerance; Prejudice

## Definition

Fear and/or intolerance of strangers, often expressed as aggression or aversion.

## Introduction

Dislike for strangers is pervasive throughout the natural world. The introduction of a strange individual often provokes the strongest aggressive responses in animals; a phenomenon termed the “xenophobic principle” by E. O. Wilson in 1975. Strangers can be a threat to one’s territory, resources, status, or mates, and consequently there is selective pressure against tolerating unknown individuals, as the costs vastly outweigh the benefits (Wilson 1975).

The result is that animals may threaten, harass, or even attack strangers. Animals may go great

lengths to avoid areas where strangers may encounter each other; at territory borders, “buffer zones” of increased prey/plant density may be created by such avoidance (Mech 1994). Borders may also be patrolled and marked to ward off intruders, or calls used to advertise the occupation of a territory (Hardouin et al. 2006; Mech 1994).

While territorial species are essentially xenophobic by definition, many group-living species are also prone to aggression towards outsiders. This is because a newcomer represents a threat to each individual’s status in the group hierarchy, thereby upsetting the existing social order (Bernstein and Gordon 1974). It is common for group members to ally with each other against intruders, including with individuals that are typically shunned (Wade 1976). Even if a group is not overtly aggressive, members may increase grooming each other in the presence of strangers, either to consolidate bonding or to make the bond more evident, in what has been term a “social shield” (Antonacci et al. 2010). After a new member joins a group, although they may appear to be tolerated, it can take months for social interactions to return to baseline levels (Fragaszy et al. 1994).

### Resource Availability

The cost of tolerating strangers varies according to the resources available. Populations of the same species may be more xenophobic in harsher, resource-poor environments, where protection of resources outweighs any potential benefits from interactions with strangers, such as reproductive opportunities (Spinks et al. 1998).

Similarly, the toleration of neighbors appears to vary depending on the level of threat they pose to an individual. In cases where there is intense competition, the result can be “nasty neighbors” (Müller and Manser 2007). However, when a neighbor poses less of a threat than a stranger, a “dear enemy” situation may arise (Fisher 1954). For example, a stranger may threaten a territory owner’s resources and territory, while a neighbor may only threaten its resources, since the neighbor already has its own territory. In this case, the

benefits of tolerating the neighbor outweigh the cost of constant vigilance and aggression (Temeles 1994). Having a neighbor that is a “dear enemy” also increases the value of the territory to the territory holder, compared to a new occupant that will have to negotiate with a new neighbor. Indeed, in great tits (*Parus major*), it has been found that new occupants initially fight more often with neighbors than the previous residents (Krebs 1982).

### Lethal Raiding

Extreme xenophobic aggression towards neighbors may take the form of “lethal raiding,” in which another group’s territory is entered and individuals are attacked by a coalitionary group. Goodall (1986) implied that chimpanzees are motivated to engage in lethal raiding due to the low cost to the aggressor, a hypothesis later developed as the “imbalance-of-power hypothesis” (Manson and Wrangham 1991; Wrangham 1999). This hypothesis predicts that attacks occur only if the raiding party has superior numbers or strength, which is borne out by field observations that have found attacks only on solitary animals or pairs by groups of at least three or more males. For safety, chimpanzees should travel in large groups, which they tend to do near borders. However, the ecological pressures of having to share limited resources (scramble competition) means that in times of reduced food availability, chimps may be forced to travel in smaller groups (Manson and Wrangham 1991). Consequently, large social networks with variation in subgroup size (fission-fusion societies) are necessary for lethal raiding, and indeed coalitionary group killing has been seen in other fission-fusion societies, such as wolves (Mason and Wrangham 1991; Mech 1994).

### Sex Differences

Sex differences in xenophobic aggression vary by species. For example, while only chimpanzee

males engage in lethal raiding and are primarily the victims of such aggression, wolves of both sexes are equally attacked and show similar aggression levels (Wrangham 1999). Whether or not the males or females of a group are aggressive to a newcomer often depends on the newcomer's sex. Sometimes, members of the opposite sex are better tolerated, or even protected from same-sex attacks (Wade 1976). Often, aggression towards strangers of the opposite sex will decrease during breeding season (Bernstein and Gordon 1974).

## Conclusion

The ubiquity of xenophobia appears to stem from the benefits of protecting territories, resources, mates, and group status from outsiders, although exceptions may be made for breeding opportunities, genetic relatives, or neighbors. Xenophobia is a major source of aggression and stress for individuals and groups, and thus an important factor to be accounted for in studies and management of animal behavior.

## Synonyms

Organ transplant; Transplant; Transplantation; Xenotransplant

## Definition

Xenotransplantation describes the movement of living cells, tissues, and organs from one species to another to describe as a defined purpose. The term xenograft has been used for the transplantation as well as inserting of organs and tissues from animals to humans. It is different from allotransplantation and autotransplantation. This procedure can overcome the shortage of donor organs. Transplantation of cells, tissues, or organs from a genetically nonidentical donor to a recipient of the same species is known as allotransplantation. Autotransplantation involves the transplantation of cells, tissues, or organs from one part of the body to another in a same person.

## Introduction

Xenotransplantation is the implantation, transfusion, and transplantation of live tissues or organs between species. Transgenic (modified genome containing foreign DNA) pigs are considered as an important animal for xenotransplantation. The structure and size of pig organs are similar enough

to humans, making them suitable for xenotransplantation. For example, pig heart valves are easily transplanted into humans. Research on xenotransplantation includes other organs, such as the kidneys, intestines, livers, lungs, and pancreas. While there are many potential benefits to xenotransplantation, there are also some concerns regarding infection by known and unknown agents.

## History

The practice of xenotransplantation began in the 1800s where skin grafts were carried out, but its practical applications are still considered difficult. Skin grafts were carried out in the nineteenth century from a variety of animals, with frogs being the most popular. Hardy in 1964 performed the first heart transplant in a human, using a chimpanzee heart, but the patient died within 2 h. The first chimpanzee-to-human liver transplantation was carried out by Starzl in 1966; in 1992, he obtained patient survival for 70 days following a baboon liver transplant. A rhesus macaque at Emory University lived for 400 days with a pig's kidney xenotransplant (Iwase et al. 2017).

## Types of Xenotransplantation

Xenotransplantation is of Four types as shown in Figure 1.

1. Solid organ transplantation – In solid organ transplantation, the whole organ such as a kidney or liver is transplanted into humans. The evolution of solid organ transplantation has progressed rapidly in the past few decades with incorporation of a variety of solid organs – the liver, kidney, pancreas, heart, and lung – into the donor pool. Porcine heart valve transplant is quite common and successful.
2. Tissue transplantation – Tissue or cells are transplanted to the recipient without any link between the animal blood vessel and the recipient blood vessel in tissue transplantation. For example, islet (pancreatic or insular tissue) tissue transplantation from a fish to a non-human primate.
3. External therapies – In this type of transplantation, the animal organ such as the liver or any

**Xenotransplantation,****Fig. 1** Types of Xenotransplantation. It is an original Diagram

other bioartificial organ circulates the human blood outside the human body.

4. **Human/animal hybrid** – Exposure to living animal-derived material, where human body fluids, cells, tissues, or organs are removed from the body; come into contact with animals cells, tissues, or organs; and are then placed back into a human.

### Barriers to Transplantation

- **Chronic Graft Rejection** – It is caused by multiple factors like antibodies and lymphocytes. Chronic graft rejection was seen in some pig cardiac xenografts. In baboons, pig cardiac xenografts lasted more than 3 months before the grafts were rejected, which functioned in baboons for greater than 3 months. Allo-transplantation leads to pathological changes in organs (Abbas and Lichtman 2005). Even after 2 years, graft vasculopathy (extended form of coronary artery disease) was not observed in the heart grafts of genetically modified pigs.
- **Cellular Graft Rejection** – The rate of cellular graft rejection for xenografts is greater than allografts (Doodeniya and Warrens 2003). Cellular graft rejection acts against the pancreatic islets, cornea, and red blood cells of pigs.

With the help of insulin-specific promoter, the desired gene can only be expressed in islets of Langerhans. Cellular grafts can be inhibited by immunosuppressive agents.

- **Hyperacute Xenograft Rejection** – Hyperacute xenograft rejection occurs when a pig organ is transplanted into humans. Hyperacute xenograft rejection is an immediate response that occurs within minutes when pig organs are transplanted into humans. These grafts are rejected within 24 h because they bind to various antibodies, such as IgM (immunoglobulin M), IgG (immunoglobulin G), and IgA (immunoglobulin A) (Taylor 2007).
- **Acute Humoral Graft Rejection** – Acute humoral graft rejection is similar to hyperacute graft rejection because it occurs very soon after transplantation. It is associated with antibody deposition that will activate the endothelium cells which in turn will affect infiltration of grafts through innate immune response and finally the graft gets destroyed.

### Advantages and Disadvantages of Xenotransplantation

#### Advantages

Xenotransplantation has numerous advantages, particularly in medical scenarios. Patients in

need of organs, for example, are more likely to receive them. This could cut down on the number of people on waiting lists and the amount of time they have to wait. Unfortunately, organs are a scarce supply, and patients' age is one of the factors that decides whether or not they will receive an organ. Because older patients survive for a shorter period of time than younger people, they are less likely to obtain organ donations. As a result, some people believe that organ donations to the elderly are a "waste" of a perfectly good organ. Xenotransplantation may enhance organ donation, making it more common. Pig organs will be more flexible with age constraints, allowing elderly patients who might usually be turned down for benefits of transplantation (Groth 2007). Many of the ethical issues that come with using organs from deceased donors will be avoided. Xenotransplantation would also allow for the pre-planning of high-quality organ transplants and the use of immunosuppressive medicines to prepare potential recipients for the procedure.

### Disadvantages

Approximately 25 of the known diseases get transferred from pig to man. Xenotransplantation brings about a lot of moral issues; many people think that using animals for the benefit of mankind is exploiting them against nature for our own needs. Animal organs have a much shorter life span than humans; if these organs get transplanted in humans, then definitely they will be dying prematurely. Therefore more and more organs will be needed for transplantation. Strong anti-rejection drugs will be needed to suppress immunity and also to make sure that it does not pose any threat to human life. Medications are poorly accepted, and most of the transplantations were not proved to be very effective.

Some ethical aspects come into the picture like animals experience both physical and psychological pain. Animals have a right to life as well. Why should animals suffer as a result of humans? The other major concern is that the majority of Jewish people did not want any part of the pig transferred. Cow transplantation is prohibited in Hinduism because it is regarded as a sacred animal.

### Statistics/Literature Available

Iwase et al. investigated the transplantation of hepatocytes from genetically engineered pigs to baboons in 2017. Oral drug administration was an issue prior to pre-clinical transplantation treatment, but Kim, Shin, and Min investigated the implantation of a gastrectomy tube for long-term medication administration in 2017. Laird, Burdorf, and French studied the lungs of genetically modified pigs in 2017 and discovered that the expression of the inhibitory ligand HLA-E increased the life of the lungs by an hour.

### Use of Biotechnology in Xenotransplantation

Biotechnology will be a great help in xenotransplantation. Looking at the prospective application of biotechnology, it seems that it will be very useful for xenotransplantation for the future since it has revolutionized the recent biological field through techniques like transgenesis, genetic engineering, cloning, site-directed mutagenesis, and several other modern techniques.

### Future Aspects

Organ transplantation would be easier if there were more donors. Xenografts used for human transplantation are destroyed within minutes by hyperacute rejection. An improved understanding of the immune recognition and rejection of xenografts has resulted in new therapies that can partially overcome hyperacute rejection (HAR). To diminish immunotransplantation, two therapies can be used, i.e., those directed at the recipient (e.g., antibodies mediated) and those directed at the donor (e.g., transgenic modifications). Moreover, increasing knowledge of the pig genome will almost certainly lead to further genetic manipulations.

## X-Linked Trait

Vishwa Gandhi

Radiation and Photo Chemistry Division, Bhabha Atomic Research Centre, Mumbai, India

## Introduction

Generally, *Homo sapiens* possess 23 pairs of chromosomes, out of which 22 pairs are autosomal chromosomes and 1 pair is of sex chromosomes. The genes present on all the chromosomes have distinct function and their expression is governed by nutrients, growth factors, hormones and other stimuli. The traits and phenotypes associated with autosomes are called *autosomal traits* which can be dominant or recessive depending upon the interaction of different alleles of the same gene. Similarly, the phenotypes associated with sex chromosomes (X and Y chromosomes) are called *sex linked traits* such as colorblindness in humans. Further, there are some traits which are influenced by sex of the individual in addition to genes on sex chromosomes. These traits are called *sex-influenced traits*. E.g. baldness in human males, irrespective of recessive homozygosity or heterozygosity, it does not express fully in females. One more similar pattern

of inheritance is *sex-limited traits* in which traits are restricted to only one sex such as breast and beard development is limited to females and males respectively, in humans.

## Sex Linked Traits

*Homo sapiens* have two types of sex chromosomes: X-chromosome and Y-chromosome. Generally, normal male is heterogametic (one X-chromosome and one Y-chromosome), while female is homogametic (two X-chromosomes). Traits or defects culminated in individual due to genes present on these sex chromosomes are called sex linked traits which can be further divided into mainly two categories depending upon the gene present on which sex chromosome:

- X-linked traits
- Y-linked traits

## X-Linked Traits

Any trait or disorder caused by genes present on X-chromosome is called *X-linked traits*. As X-chromosome is present in different numbers in male and female, its inheritance pattern is different than autosomal chromosomes. Further, X-linked inheritance can also be of two types depending upon the nature of the allele (recessive/dominant) involved in appearance of phenotype/disorder:

- X-linked recessive inheritance.
- X-linked dominant inheritance.

## X-Linked Recessive Inheritance

*X-linked recessive inheritance* is pattern of inheritance in which responsible allele or mutation of gene for particular disease or trait is expressed only when it does not masked by normal/dominant allele. Such situations are normal in males (hemizygous for mutated allele) and females with homozygous for mutated allele on X chromosome. Disorders inherit in this pattern appear in males as a result of mutation in hemizygous gene; while in females; major reason

for this type of defects is random inactivation of X chromosome (lyonization). Some of the characteristic features of X-linked recessive traits are as follows:

- Mainly males of the family are affected.
- Sons of the affected father are not affected by the trait.
- Daughters of affected father and normal mother are always carrier.
- Daughter is only affected when father is affected and mother is carrier (50% chance) or affected (100% chance).
- Son of affected female is always affected, while 50% of chances of carrier female to have affected son.
- There is no carrier male in this type of inheritance.

As depicted in Fig. 1, couple of carrier female and unaffected male may have affected or unaffected sons depending on the genotype of X chromosome coming from mother (mutated or normal). But all the daughters of the couple are either carrier or normal as father provides X chromosome with normal genotype for the trait.

Some of the examples and case studies for disorders inherit in X-linked recessive pattern are given below:

### Glucose-6-Phosphate Dehydrogenase Deficiency

Glucose 6 phosphate dehydrogenase (G6PDH) is an important enzyme for pentose phosphate pathway in glucose metabolism. Deficiency of this enzyme is inborn error which leads to breakdown of red blood cells. This enzyme is coded by 18.5 kbp gene present in Xq28 band on long arm of X chromosome. Mainly, nucleotide substitution and nucleotide polymorphism are responsible for mutation in this gene. Mainly G6PDH deficiency causes hemolysis (red blood cells degradation) which in turn culminates into neonatal jaundice, ketoacidosis, kidney failure, etc. Sometimes condition gets worst in response to some drugs (drug induced hemolytic anemia), some chemicals and beans (favism). By avoiding use of Fava beans and some drugs such as aspirin, quinine, antimalarial drugs, this condition can be managed. It can also be managed by folic acid supplementation and blood transfusion.

### Color Blindness

It is the condition a person with disability to recognize color or difference in color shades. Most common form of color blindness is red-green color blindness, followed by blue-yellow color blindness and then complete color blindness. In this defect, genes responsible for development of one or more or all three cones present on X chromosome are

#### X-Linked Trait,

**Fig. 1** Representative pedigree chart showing inheritance pattern of X linked recessive trait

mutated. Colorblindness cannot be cured. Due to its inheritance pattern, it is more prevalent in males (8%) then women (0.5%) in Northern Europe. In addition to X linked recessive mutation, other factors such as Vit. A deficiency (Leikin et al. 2003), exposure to some solvents (Dick 2006), ethambutol-a drug used for treatment of tuberculosis (Polak et al. 1985) are some of the causative agents for color blindness.

### Hemophilia

Hemophilia is a blood clotting disorder, in which affected person is having mutation in blood clotting factors which results in prolonged blood clotting time. Hemophilia is of two types: hemophilia A (deficiency in clotting factor VIII) and hemophilia B (deficiency in clotting factor IX/Christmas factor deficiency). Genes coding for clotting factor VIII and clotting factor IX are present on Xq27.1 and Xq28 location on X chromosome, respectively. Most common feature of hemophilia is episodes of internal as well as external bleeding and its frequency depends on the severity of disorder. One of the advanced therapies for hemophilia is gene replacement therapy.

### Case Study: Hemophilia in Queen Victoria Family

Hemophilia has also been known as Royal disease because many members of family of Queen Victoria are affected by this disorder. As it is X linked recessive disorder, majorly males of the family are affected as shown in the family tree. In last generation, most of the descendent had hemophilia, which led to their early death caused by some injuries and excessive internal or external bleeding (Wayback Machine 2006). The type of the hemophilia remained unidentified as last member of Queen Victoria family was died in 1940.

In 2009, some researchers have figured it out that it was hemophilia B what was inherited in descendents of Queen Victoria (Rogaev et al. 2009) (Fig. 2).

Some of the other disorders inherit by X linked recessive pattern are as listed below:

| Disorder/trait                                    | Characteristic features                                                                                                                                                                                      |

### X-Linked Dominant Inheritance

When allele responsible for particular trait of disease is dominant in nature (does not affected by presence or absence of other allele of same gene),

**X-Linked Trait, Fig. 2** Inheritance of hemophilia B in Queen Victoria and her descendents (Red boxes indicating affected individuals in family tree). (Photo: Wikipedia/Shakko)

present on X chromosome is called X-linked dominant gene and inheritance pattern conferred by that gene is called *X linked dominant inheritance* or *X linked dominance*. Due to its dominant nature, only one copy of allele is sufficient to develop disease condition or any other particular trait. Some of the characteristic features of X-linked recessive traits are as follows:

- Unlike X linked recessive inheritance, males and females both are affected by the trait in family.
- Daughter of affected father is certainly affected by trait of interest.
- Appearance of trait in daughter of unaffected father is solely depending on genotype of affected mother. If mother is heterozygous,

there is 50% chance of affected daughter, while daughter is certainly affected if mother is homozygous for gene for interest.

- Son of affected father and unaffected mother is unaffected.
- Son of affected mother have 50% of chance to be affected if mother is heterozygous and son is certainly affected if mother is homozygous for gene for interest.

As depicted in Fig. 3, couple of normal female and affected male has affected daughters because of the X chromosome coming from father. But all the sons of the couple are normal as father provides Y chromosome and mother provides X chromosome with normal genotype for the trait.

Some of the examples and case studies for disorders inherit in X-linked dominant pattern are given below:

### X Linked Hypophosphatemia (XLH)

It is also known as X linked dominant form of rickets. Mutation in *PHEX* gene present on X chromosome (Xp22) is responsible for the demineralization of bones and renal wastage of phosphate, which ultimately leads to development

of rickets like symptoms such as soft bones, osteoarthritis, dental problems, hearing loss etc. XLH differentiate itself from autosomal rickets by being not cured by Vit. D supplements. Therefore, it is also known as X linked Vit. D- resistant rickets. Its occurrence rate is 1:20000. Surgery of leg deformities and supplements such as phosphate, calcitriol, human growth hormone helps to palliate the symptoms.

### Fragile-X-Syndrome

It is the second most common genetic cause of mental retardation. Mutation in *FMR1* gene present on X chromosome at location of Xp27.3. This disorder is also characterized as triple repeat expansion disease as CGG repeats (5–40 repeats) present in 5'-UTR of *FMR1* gene expands to 200 repeats which leads to deficiency of fragile X mental retardation protein (FMRP). FMRP is important protein for development of normal synaptic connections. Deficiency of this proteins leads to neurological and mental disabilities. Symptoms of this disorder include autism, mental retardation, difficulties in social interactions, infertility, macroorchidism, hypotonia etc. There is no cure for this disease.

### X-Linked Trait,

**Fig. 3** Representative pedigree chart showing inheritance pattern of X linked dominant trait

### Craniofrontonasal Dysplasia

It is very rare disease caused by X linked gene with dominant mutation in ephrin-B1 gene (*EFNB1*). Ephrin-B1 binds to ephrin receptor which has very important role in embryonic tissue border formation via cell-cell interaction. Deficiency of EFNB1 causes disturbance in cell-cell interaction and ultimately leads to skeletal and craniofacial malformation. Other characteristic features of this disorder are webbed neck, fizzy curly hairs, bifid nasal tips, facial asymmetry, craniosynostosis of the coronal suture, clinodactyly, syndactyly, scoliosis etc. Deformities can be treated by surgery up to certain extent.

Some of the other disorders inherit by X linked recessive pattern are as listed below:

| Disorder/trait                                   | Characteristic features                                                                                |
|--------------------------------------------------|--------------------------------------------------------------------------------------------------------|
| Rett syndrome Amir et al. (1999)                 | Mutation in <i>MECP</i> gene on X chromosome                                                           |
|                                                  | Prevails in 1:10000 females                                                                            |
|                                                  | Autistic features, panic attacks, seizures, tremors                                                    |

|                                                  | Blistering, wart-like rashes                                                                           |
|                                                  | Hypopigmentation                                                                                       |
|                                                  | Hypodontia                                                                                             |
|                                                  | Alopecia                                                                                               |
| Alport Syndrome Jais et al. (2003)               | Affects central nervous system                                                                         |
|                                                  | Mutations in COL4A3 (autosomal recessive), COL4A4 (autosomal recessive) and COL4A5 (X-linked dominant) |

(continued)

| Disorder/trait | Characteristic features                                         |
|----------------|-----------------------------------------------------------------|
|                | Deficiency of one of the structural proteins called collagen IV |
|                | Vision and hearing impairments                                  |
|                | Leiomyomatosis                                                  |

Despite of all these studies regarding inheritance pattern of X-linked traits, some traits fail to follow recessive and dominant inheritance pattern in females because of random inactivation of one of the two X chromosomes present in females. Because of this irregularity of inheritance pattern, many researchers suggest to discontinue to classify X linked traits into dominant and recessive.

### X-Linked Traits in Other Animals

XY-sex determination system is observed in many other species which also show phenotypes inherit in X linked pattern. Fur color of domestic cats is governed by X linked *O/o* gene. *O* gene is responsible for orange color fur which is co-dominant with its non-orange counterpart allele *o*. Presence of *O/o* gene can mask effect of gene of any other color. Another example is lacticolor gene in magpie moth with inheritance pattern of X linked recessive.

### Y-Linked Traits

Appearance of phenotypes as a result of expression of genes present on Y-chromosomes is called *Y-linked inheritance*. It is also known as *holandric inheritance* and it can pass from father to son only. Azoospermia is one of the examples of Y-linked inheritance. In which, AZF region on Y-chromosome responsible for synthesis of protein require for sperm production is deleted in some males and leads to inability of sperm production. As normal males have single Y-chromosome, the defect on Y-chromosome cannot be recovered (hemizygous). So, Y-linked inheritance does not occur in females while males cannot be escaped from Y linked defects

if their precedents are affected with Y linked disease.

## Yerkes Primate Research Center

Tiffany A. Baker  
University of Southern Mississippi, Hattiesburg,  
MS, USA

approximately 3,400 nonhuman primates and 13,000 rodents across two locations, the main center and the field station. The 25-acre main center is located on the campus of Emory University, and houses approximately 1,200 primates, as well as the biomedical laboratories of Yerkes National Primate Research Center. Also at the main center, the Yerkes vivarium contains around 13,000 rodents. Much larger, the field station expands 117-acres in Lawrenceville, Georgia, and houses about 2,200 primates. As opposed to the main center, behavioral research is most often conducted at the field station partly because the field station provides a more naturalistic setting. Moreover, breeding is carried out at the field station. For the functioning of both facilities, Yerkes National Primate Center has over 400 faculty, researcher, and staff employees (Emory [2017](#)).

## Synonyms

[Yerkes Research Center](#)

## Introduction

Yerkes National Primate Research Center is the first nonhuman primate research facility established in the United States of America (Dewsbury [2006](#)). Now a division of the Robert W. Woodruff Health Sciences Center at Emory University in Atlanta, Georgia, it is home to

## Directors

As of 2017, R. Paul Johnson, MD, maintained position as director of the Yerkes National Primate Research Center beginning in the year 2014. Johnson has been board certified in Internal Medicine with a Certification in Infectious Diseases. He obtained his Bachelor's degree in Psychology from Duke University, and his medical degree from Harvard Medical School (Emory [2017](#)).

Nine other individuals have served as the director of Yerkes National Primate Research Center. These include, in reverse chronological

order, Stuart Zola (2002–2014), Thomas P Gordon (1999–2002), Thomas R Insel (1994–1999), Frederick A King (1978–1994), Geoffrey Bourne (1962–1978), Arthur J Riopelle (1959–1962), Henry W Nissen (1955–1958), Karl Lashley (1942–1955), and Robert M Yerkes (1929–1941; Borden 1995; Dewsbury 2006; Hilgard 1965). No women have held the position.

## History

Robert Mearns Yerkes, an American comparative psychologist, established the Yerkes National Primate Research Center in 1930 under the name Yale Laboratories of Primate Biology. In 1924, Yerkes accepted a professorship at Yale University with the exclusive aim of founding the first nonhuman primate laboratory focused on the systematic and continuous study of non-human primates and their relations to man. Yerkes recognized the significance and advantages of primates as comparative research subjects, and was dedicated to opening a facility that made such possible (Yerkes 1930). Prior to his tenure with Yale University, Yerkes published the “Provision for the Study of Monkeys and Apes” in *Science* proposing guidelines for the establishment of a primate facility allowing for behavioristic, psychological, sociological, and genetic inquiries. Within the 1916 article, Yerkes outlined facilities that would allow for the health and well-being of different types of primates as well as facilities that were conducive to breeding and child rearing. He proposed that observations should be possible under natural conditions, and that research should be conducted from every significant biological point of view. Following a similar principle, he called for the economical use of primates, which he defined as the continuous use of a primate throughout its life span. Under these circumstances, Yerkes claimed that the high cost of breeding and maintaining the animals would be offset. In addition, Yerkes believed the center would bring currency flow by allowing other institutes to make use of the facilities and animals (Dewsbury 2006; Yerkes 1916).

Prior to the opening of Yale Laboratories of Primate Biology in 1930, Robert Yerkes purchased a chimpanzee, Panzee, and a bonobo, Chim, from Noel Lewis. Lewis paid to house his apes at the New York Zoological Park. In 1923, the park director, William T. Hornaday, notified Yerkes of Lewis’ interest in selling the animals. Yerkes then purchased both Chim and Panzee for a total of \$2000, a steep price for the apes at the time. It is unknown why the apes were so expensive as chimpanzees commonly sold for \$200–\$300 per animal (Dewsbury 2006). The two chimps lived in a bedroom at Yerkes’ home, and were taught to behave like human children. Yerkes documented this experience in his 1925 book *Almost Human* (Hilgard 1965; Yerkes 1925). Chim and Panzee were the first of many apes Yerkes would eventually purchase (Dewsbury 2006).

In 1929, the Rockefeller Foundation provided the main source of funding for the opening of Yale Laboratories of Primate Biology. The Carnegie Institute of Washington lent additional support (Dewsbury 2006). Yerkes moved to New Haven, Florida, an environment more conducive to non-human primates, and established the Yale Laboratories of Primate Biology in Orange Park, Florida (Yerkes 1930). The locals in the surrounding area referred to the facilities as the monkey farm (Dewsbury 2006), a nickname that has persisted.

The founding colony at Yale Laboratories of Primate Biology consisted of four animals moved from Connecticut to Florida with Robert Yerkes, 13 chimpanzees that were donated from Madam Rosalia Abrue’s private collection in Cuba, and 16 apes donated from France (Dewsbury 2006). Moreover, the birth of the first chimpanzee, named Alpha, at the Yale Laboratories of Primate Biology occurred during the initial year of operation, allowing the collection of data pertaining to reproduction and development (Dewsbury 2006). During Yerkes tenure as director, 90 chimpanzees were studied. After his resignation in 1941, the center was renamed Yerkes Laboratories of Primate Biology in honor of his contributions to science (Hilgard 1965).

Robert Yerkes passed away in 1956 requiring Yale officials to make difficult decisions pertaining to the geographical location. Because

Yerkes Laboratories of Primate Biology was in Orange Park, Florida, it was difficult for Yale faculty and students to make use of the facility and primates. Therefore, Emory University agreed, in 1956, to assume ownership of the Center. As a result, Emory University became the host institution and Yerkes Laboratories of Primate Biology was transferred to Atlanta, Georgia, where it remains today (Hilgard 1965). Funding from the National Institutes of Health (NIH) made the transfer possible, with the field station opening shortly after in 1966 (Dukelow and Whitehair 1995).

### National Institutes of Health

In the late 1950s and early 1960s, Congress was becoming increasingly aware of the benefits of nonhuman primate models when investigating human health and well-being. Therefore, in 1960, the National Institutes of Health's Primate Research Program was created to govern the establishment of six additional regional facilities as well as the reorganization of Yerkes Laboratories of Primate Biology to Atlanta, Georgia. These seven facilities became known as National Primate Center. They are sponsored by the National Institutes of Health to conduct biomedical and behavioral research with nonhuman primates, and are responsible for conducting research regarding infectious and noninfectious diseases (Dukelow and Whitehair 1995).

In 2002, Yerkes Laboratories of Primate Biology became the Yerkes National Primate Research Center, a name that reflects its participation in the federally funded program (Borden 1995). Yerkes National Primate Research Center is the oldest of the seven National Primate Centers in the United States of America (Dukelow and Whitehair 1995).

Yerkes National Primate Research Center and Washington National Primate Research Center are the only two National Primate Centers that have field stations. In addition, only Yerkes National Primate Research Center and the Wisconsin National Primate Center have collaborated with zoos (Dukelow and Whitehair 1995).

### Vision, Mission, and Values

Per the Emory University (2017) website, Yerkes National Primate Research Center's Vision is "to be recognized nationally and internationally as a leading center for both basic and applied research that involves our nonhuman primate colony and other animal species strategically in the service of humanity." Its mission is to "conduct essential basic science and translational research to advance scientific understanding and to improve the health and well-being of humans and non-human primates. They provide leadership, training, and resources to foster scientific creativity, collaboration and discoveries. Yerkes-based research is grounded in scientific integrity, expert knowledge, respect for colleagues, and open exchange of ideas and compassionate, quality animal care." The Yerkes National Primate Center's values are "stewardship, excellence, integrity, collegiality, and people."

### Regulatory Bodies

Yerkes National Primate Center follows regulations and guidelines established by the National Institute of Health, the United States Department of Agriculture, and Emory's Institutional Care and Use Committee. Yerkes National Primate Center also maintains compliance with the regulations of the Animal Welfare Act (Emory 2017), a federal statute passed in 1966 that governs the humane treatment of animals (Cohen 2006).

### Animals

The Yerkes National Primate Research Center has approximately 3,400 nonhuman primates (Emory 2017) acquired from either a licensed breeder for animal research or bred at Emory (Borden 1995). The rhesus macaque participates most often in experiments. Other primates include the chimpanzee, sooty mangabey, squirrel monkey, and cynomolgus monkey. In addition to primates, approximately 13,000 rodents are housed at the Yerkes National Primate Research Center, and are

frequently the first animal model used in research programs at the center. Yerkes vivarium contains rodents including mice, rats, and voles (Emory 2017).

The animal care staff, including clinical veterinarians, veterinary technicians, a research nurse, and animal care technicians, provide continuous oversight 365 days a year. Since 1985, Yerkes National Primate Research Center has been accredited by the Association for Assessment and Accreditation of Laboratory Animal Care International (AAALAC). Accreditation through this private, nonprofit organization, which promotes the welfare of animals (Goodman et al. 2015), is considered the gold seal of approval for laboratory animal care (Borden 1995; Goodman et al. 2015).

Yerkes National Primate Research Center utilizes a behavior management program that emphasizes the opportunity to socialize. In addition, the program includes the environmental enrichment opportunities which includes feeding, structural, physical, and sensory enrichment. As per the behavior management program, the training program, including training related to health services, is based on positive reinforcement (Emory 2017).

## Research

Yerkes National Primate Research Center is home to a nonhuman primate DNA Bank, which serves Emory University but also outside initiatives. Research is divided into seven service cores: Biomarkers Core, Comparative Aids Core, Molecular Pathology Core, Nonhuman Primate Genomics Core, Tetramer Core, Virology Core, and Yerkes Imaging Core. Because the research program at Yerkes National Primate Research Center is large and potentially cumbersome, the division into cores services facilitate maximum use of resources and technology for investigators (Emory 2017).

Not only do scientists within Emory University have access to the resources available at Yerkes National Primate Research Center, but outside scientists are strongly encouraged to collaborate

and make use of the facilities. Yerkes National Primate Research Center, as well as the seven other National Primate Centers are considered national resources (Dukelow and Whitehair 1995).

## Zero Concept

Irene M. Pepperberg  
Department of Psychology, Harvard University,  
Cambridge, MA, USA

### Definition

“Abstract symbol for the absence of quantity.”

### Introduction

Mention “zero” in conversation (“There is zero chance of that happening...”) and the average person understands what is implied. However, like many other concepts, that of zero can formally be defined in different ways. Most commonly, it is used to refer to a null set, but it can also be used as a placeholder to indicate absence.

The latter use is likely the first to have been developed (possibly as early as 1500 BCE; Neugebauer 1957) and is interesting because the ability to understand and comment upon absence, although seemingly simple, denotes a relatively advanced stage in cognitive and linguistic development (Brown 1973). An organism reacts to absence only after acquiring a corpus of knowledge about the expected *presence* of events, objects, or other information in its environment, that is, only when a discrepancy exists between the expected and actual state of affairs (de Villiers and de Villiers 1979; Hearst 1984; Pepperberg 1988; Skinner 1957). Human use of a particular symbol to represent the absence of a numerical set took considerably longer to develop (likely ~300 BCE; Kaplan 2000), but, again, it was then also merely a placeholder. Use of zero as a specific digit likely originated in Asia sometime between the fifth and seventh centuries AD (Bourbaki 1994). It was not until the 1600s, however, that use of zero in computation became widespread in Western civilization, probably through the work of Newton and Leibniz.

### Children’s Understanding and Use of Zero

Given this history, and the acquisition of numbers by human children as a means to quantify specific, existent sets of items, it is not surprising that understanding and formal use of zero

(a noncountable entity) occurs only after basic numerical knowledge has already been acquired: Bialystok and Codd (2000), Merritt and Brannon (2013), and Wellman and Miller (1986), for example, have all shown that children acquire understanding of zero slowly and in stages. Some as young as 3 years old may understand that a set consisting of “no cookies” can be represented by a blank sheet of paper (Bialystok and Codd 2000). They may recognize and name the symbol before using it appropriately (i.e., at about 4 years old; Wellman and Miller 1986), but often do not begin to understand that it represents a quantity less than “1” until about 4–5 years old (Merritt and Brannon 2013; Wellman and Miller 1986), or to use the symbolic notation “0” routinely until around 5 years of age, well after understanding formal counting. Only at about 6 years do they understand that the symbol does not affect quantity in operations such as  $n \pm 0 = n$  (Wellman and Miller 1986).

Even in adults, appropriate use of zero is not universally understood, particularly with respect to multiplication and division (Miller et al. 1984; Wheeler and Feghali 1983). Zero also is unique in that it is not generally considered as part of, or the start of, the number line (Brysbaert 1995). Asked to “count,” adults are enculturated to begin “one, two...” Thus zero is not generally viewed the same way as are other numerical symbols. What then might be its evolutionary roots?

## Nonhuman Animals and Absence

Ethologically, absence or nonexistence is an important concept. Absence of food obviously triggers foraging behavior, but nonhumans exhibit other positive behaviors correlated with absence of certain signals. Birds, for example, react to the absence of signs of territorial defense (e.g., song) from conspecific neighbors with positive acts of territorial invasion (e.g., red-winged blackbirds, Peek 1972; Smith 1979). Such behavior may, however, also be interpreted as the removal of a factor that was inhibiting its expression (a neighbor ready to attack) rather than as specific recognition of “absence” (Pepperberg 1988).

Some nonhuman subjects were taught to express absence more formally: Chimpanzees (*Pan troglodytes*) and a dolphin (*Tursiops truncatus*), trained to communicate via symbolic representation, could comment on the absence of expected items (apes via ASL [Gardner and Gardner 1978] or Yerkish [Rumbaugh and Gill 1977]; the dolphin via touching yes/no paddles [Herman and Forestell 1985]). A Grey parrot (*Psittacus erithacus*) learned to use English speech referentially to respond to the absence of similarities or differences between two objects (e.g., responded to “What’s same/different?” with “none” if the objects were, respectively, completely different or identical; Pepperberg 1988). This parrot, Alex, also spontaneously transferred use of “none” to respond to the absence of a size differential the first time he was asked to label the color of the bigger or smaller item in an equally sized pair (Pepperberg and Brezinsky 1991). These instances, although providing evidence for symbolic understanding of absence, had little to do with symbolic representation of a null set – the numerical zero.

## Nonhumans and Zero-Like Concepts

No nonhuman has acquired a concept of zero identical to that of adult humans. Nevertheless, several nonhumans have exhibited behavioral precursors similar to those of young children, such as monkeys (*Macaca mulatta*) who appropriately represent empty sets along a continuum (Merritt and Brannon 2013; Merritt et al. 2009). Interestingly, specific neurons in the parietal cortex of the snow monkey (*Macaca fuscata*) respond to a null set (Okuyama et al. 2015): Shown a target numerosity (0–4) and then a second quantity (0–6), monkeys could add or subtract objects in the second quantity to match the target for a reward. Implanted electrodes in their ventral intraparietal area showed that specific neurons fired only when monkeys viewed a target of 0 and again when the target 0 was matched; different neurons responded to 1–4.

Only a few nonhumans have, however, achieved symbolic representation of a zero-like

concept. Chimpanzees, for example, were actively trained to match various numerical arrays to Arabic numerals, to then match an empty set with the 0 numeral and finally to match 0 to an empty set (Biro and Matsuzawa 2001; Boysen and Berntson 1989). All eventually succeeded at statistically significant levels, thereby demonstrating both production and comprehension, which is critical for claiming symbolic representation (see Savage-Rumbaugh 1986). However, one of these subjects, Ai, had difficulty understanding the ordinality of zero; that is, when asked to rank 1 versus 0, she might confuse the two and, like young children, rank 1 as less (Biro and Matsuzawa 2001; Wellman and Miller 1986). One chimpanzee, Sheba, did appropriately rank 0 versus 1 (Boysen et al. 1993) and understood the symbolic  $n + 0 = n$  concept (Boysen and Berntson 1989). (Note: Chimpanzees in another study seemed to understand  $n + 0 = n$  in a nonsymbolic summation task, although that data could alternatively be interpreted as the subjects having learned to avoid an empty container; Rumbaugh et al. 1987.) The aforementioned parrot, Alex, spontaneously transferred his use of “none” to label the absence of a specified numerical set (Pepperberg and Gordon 2005): If given trials with differently colored sets in which the targeted set was absent (e.g., “What color six?” when no set of six existed), he did not respond with the label indicating a set close in number but rather with the label “none,” demonstrating that he knew that the exact set was missing (Pepperberg, this volume; Pepperberg and Carey 2012). He, like Sheba, also understood that a quantity plus a null set should be labeled the same amount as the original quantity (Pepperberg 2006, 2012), but if asked to sum *two* empty sets, did not use “none” appropriately (Pepperberg 2006). He died before he could be trained to use the 0 symbol and be tested on understanding its ordinal relationship to other Arabic numerals.

## Conclusion

Zero represents absence of quantity, and performance on tasks involving absence is generally

lower than on those involving presence (even on tasks matched for difficulty; Hearst 1984); it is therefore not surprising that human symbolic use and understanding of zero historically occurred later than use and understanding of other numerals, and also does so developmentally. Although a basic response to absence (e.g., of food, water) is clearly an ancient evolutionary trait, encoding that basic understanding symbolically is a nontrivial accomplishment, both for humans and nonhumans. Given that only a very few nonhumans have acquired symbolic representation of number and concepts of cardinality and ordinality (e.g., Pepperberg, this volume), it is also not surprising that only a subset of those nonhumans have successfully acquired something akin to the human concept of zero.

## Zigzag

### ► Zigzag Display

---

## Zigzag Display

Madeline Redd and Kristine O. Evans  
Department of Wildlife, Fisheries and  
Aquaculture, Mississippi State University,  
Mississippi State, MS, USA

## Synonyms

Attraction; Avoidance; Disruptive; Evasion; Zigzag

## Definition

Zigzag display includes a series of short, sharp turns, angles, or alterations in a course or direction

involved in several survival and reproductive behaviors.

## Introduction

Zigzag display is a goal-oriented behavior, which facilitates predator avoidance and mate attraction for some species. As a strategy, zigzag display has been shown to enhance survival and reproductive success, ultimately leading to fitness benefits for a species.

## Breeding Behavior

Zigzag display is evident in males of several species as a means to demonstrate quality as a potential mate. These body movements are an important determination in individual reproductive success. Most of the species exhibiting this strategy develop elaborate dance-like behaviors that include sharp or zigzag movements to signal courtship. The three-spine stickleback (*Gasterosteus aculeatus*), a fish species native to northern coastal waters, uses zigzag display as a component of its breeding behavioral repertoire. Males of this species build a nest and exhibit zigzag dancing movements during courtship to attract nearby females in an attempt to secure a mate. The three-spine stickleback male uses its caudal fin to propel dirt in a zigzag fashion to attract the female's attention to the nest that the male has provisioned (Jun et al. 2008). The zigzag dance has been shown to increase mating success in males that attract females to oviposit in the male's nest.

Zigzag display occurs across a wide variety of breeding behaviors in several other species as well. Manakins of the Family Pipridae are a group of bird species known for their elaborate courtship dances that use zigzag display to attract females. Female manakins choose their mates based off the male's courtship performance (Barske et al. 2011). The more favorably the female perceives the male's agility and swift movements during zigzag display, the better the male's chances for mating success during courtship. Kingbirds (*Tyrannus* spp.) have long been

shown to use a zigzag flight display to attract females during courtship (Townsend 1920). This bird species uses a very displeasing courtship dance to the human eye; however, the males that are successful with the display have increased chances of reproductive success.

## Predator Avoidance (Escape Behavior)

The ability for prey to escape or avoid predators is critical to individual survival. Animals of many species have adapted countermeasures to predator hunting strategies to increase chances for survival. In the predator avoidance context, the zigzag display is a series of distracting movements intended to disorient a predator and slow the forward trajectory of a predation attempt. A study assessing success in avian predators showed that zigzag display behavior in snakes was a greater determinant of successful predator avoidance than disruptive coloration (Niskanen and Mappes 2005). Some scientists believe that erratic zigzag displays cause disruption in the mechanisms driving predator attack behavior when responding to the prey's erratic movements (Humphries and Driver 1970). Gazelles, rabbits, and other herbivores are known for using erratic zigzag movements to escape the grasp of predators. In FitzGibbon (1993), the author investigated outcomes of increasing distance between prey and predator in gazelles as a result of zigzag patterns of movement and found that risk of predation decreased in older gazelles due to improved agility and capacity for sharp movements exhibited during zigzag display.

## Conclusion

Zigzag display is a metabolic investment for an individual exhibiting this behavior but provides important potential survival and reproductive benefits. The behavior has been defined as an erratic movement to advance the animal's fitness, and studies clearly demonstrate direct linkages between fitness and zigzag escape

and courtship behavior. Prey species take advantage of the agility and speed of the zigzag movement to reduce risk of predation. Males of some species may also use the attention-grabbing movements of the zigzag display during courtship to enhance likelihood of being chosen by a female as a mate.

## Zöllner Illusion

Michael J. Beran<sup>1</sup>, Audrey E. Parrish<sup>2</sup> and Christian Agrillo<sup>3</sup>

<sup>1</sup>Department of Psychology, Language Research Center, Georgia State University, Atlanta, GA, USA

<sup>2</sup>Department of Psychology, The Citadel, Charleston, SC, USA

<sup>3</sup>University of Padua, Padua, Italy

Visual illusions involve experiences of perceiving visual stimuli in ways that do not align with reality. These illusions take many forms, including illusions of numerosity, movement, and size. These illusions as experienced by humans are often also experienced by nonhuman animals. The comparative perspective on visual illusions has provided a wealth of information about how visual processing works across species, highlighting potentially conserved and evolutionarily ancient mechanisms that represent the visual world incorrectly. These illusions are valuable also as a means to understanding how visual perception works.

One important visual illusion is called the Zöllner illusion. This illusion is characterized by how humans respond to viewing two parallel lines that appear to be convergent when oblique cross-hatches are superimposed on them (see Fig. 1, column 3). There has been debate about why this illusion occurs in humans, and potential causes include the crucial contribution of acute angles within the visual array (see Kitaoka and Ishihara 2000; Oyama 1975; Wallace 1969) and the role of global characteristics of stimulus configuration (Parlangelì and Roncato 1995).

There have been only a few comparative studies of this illusion. As with many visual illusions, the Zöllner illusion has been studied in other species relative to how humans experience the illusion. This has meant determining whether other animals show the same bias for convergence of lines. The earliest study was conducted with two baboons (Benhar and Samuel 1982) that were tested in an oddity task. Monkeys were trained to

## Zinc Finger Nuclease

- [Targeted Mutation](#)

**Zöllner Illusion, Fig. 1** Example of testing stimuli from Agrillo et al. (2014). Monkeys were trained to select the narrower gap between the lines' edges. In the training phase (a), convergences of the main lines ranged from 15 to 12°. In the test phase (b), more difficult

discriminations were presented (11–1°), including parallel lines. For each phase three different conditions were presented: control (no crosshatch), perpendicular (90° crosshatches), and Zöllner (30° crosshatches) condition

select the odd stimulus within a set of three images. When presented with two parallel lines, two convergent lines, and the “Zöllner” lines (parallel lines with crosshatches), they indicated that the odd stimulus was the one with parallel lines. Benhar and Samuel (1982) suggested that this indicated that baboons perceived the Zöllner lines as being like the convergent lines, both of which were unlike the parallel lines.

The second study of this illusion was conducted with pigeons (Watanabe et al. 2011). The birds were trained to peck at the narrower (or wider) of two gaps at the end of a pair of lines that converged toward one end. Then, they were given the Zöllner lines in some test trials. If the birds experienced an illusion, then they would be more likely to peck one end of the Zöllner lines or the other, presumably because the lines would appear to be similar to the actually converging or non-converging lines used in training. Interestingly, the pigeons pecked toward the end of the

Zöllner lines that appeared to deviate (i.e., their behavior was opposite to humans who would select the end of the Zöllner lines that appeared to converge). The same pattern of behavior was found in a subsequent test with the bantam (Watanabe et al. 2013). These two studies suggest that birds may perceive this illusion very differently than do humans.

The reversed illusion as perceived by two avian species may reflect a reduced sensitivity to contrast effects which are thought to play a role in the emergence of the Zöllner effect as well as other illusions. Contrast leads to the overestimation of differences between the features of stimuli within an illusory array. Assimilation, on the other hand, leads to the underestimation of stimulus features. Watanabe et al. (2013) suggested that pigeons and chickens underestimated the acute angles between each main line and its crosshatches, as those animals assimilated the crosshatches with the main line. This may account for the reversed Zöllner

illusion. These results are similar to the reversed effect seen among avian species for other well-known visual illusions (e.g., the Ebbinghaus-Titchener size illusion; Nakamura et al. 2008).

Most recently, Agrillo et al. (2014) assessed whether rhesus monkeys perceived the Zöllner illusion and whether any such illusion matched the direction seen in humans. Monkeys were first trained to select the narrower end of two lines when there really was convergence (Fig. 1, top left). After learning to do this, some probe trials presented parallel lines without hatches (Fig. 1, bottom left), converging lines with perpendicular (90°) crosshatches (Fig. 1, top middle), parallel lines with perpendicular (90°) crosshatches (Fig. 1, bottom middle), and converging or parallel lines with Zöllner (30°) crosshatches (Fig. 1 top right and bottom right, respectively). It is important to note that perpendicular crosshatches are known not to generate any orientation illusion in humans. Therefore, if monkeys perceived the Zöllner illusion, they were expected to exhibit a bias only in the presence of 30° crosshatches. Monkeys chose the end of the parallel lines with the 30° crosshatches in the same way as humans who show the Zöllner illusion, whereas for parallel lines with no crosshatches or 90° crosshatches, they choose at random between the two ends. Thus, rhesus monkeys showed a human-like pattern and one opposite to that of birds. Unlike birds, nonhuman primates appear to be sensitive to both contrast and assimilation mechanisms as evidenced in the perception of a variety of visual illusions that reflect both effects (e.g., the Delboeuf size illusion; Parrish et al. 2015). In this case, it is possible that – by contrast – monkeys enlarged the subjective perception of acute angles between the main lines and crosshatches. More research is needed to understand the causes of these comparative differences and may provide new insights in aspects of visual illusions.

## Zoo

Terry L. Maple  
Georgia Tech (retired), Fernandina Beach,  
FL, USA

In the twentieth century, world zoos began to redefine their purpose. They also began to think of zoos and aquariums collectively and elevate operating standards and practices (Barongi et al. 2015) to meet or exceed public expectations. Achieving zoos worldwide began to differentiate themselves from those without a rigorous accreditation process, thereby reducing the number of

institutions that can be legitimately identified as a zoo. Zoo professionals who work for accredited institutions understand the difference between those who belong and those who do not. The public, however, is not as discriminating. Because they tend to lump all facilities that exhibit animals together, accredited zoos are too often criticized for offenses they have not committed. In North America's Association of Zoos and Aquariums (AZA) as of September 2018, there are 233 institutional members, while there are literally thousands of USDA-licensed nonaccredited animal exhibitors in the United States and thousands more throughout the world. A common difference between the two categories are the propensity of nonaccredited facilities to encourage close contact between visitors and animals, e.g., rides, petting zoos, and intimate photo opportunities. For accredited zoos and aquariums, such risky practices are considered an ethical breach. But this distinction is complicated since there are some exceptions such as supervised swimming with dolphins in some aquatic parks such as SeaWorld and the ubiquity of touch tanks in many otherwise highly regarded institutions. Contact with confined zoo animals is a delicate subject since it is known that contact between animals and human visitors promotes bonding that enables respect and support for animals. If contact is permitted, it must always be carefully regulated, monitored, and justified. Because Millennials in particular, have shown a disdain for zoos, it is essential that accredited institutions send clear messages to their guests, members, and donors. Zoos must stand for noble values by choosing to be global leaders in conservation, education, and animal welfare (Norton et al. 1995). Exotic and endangered species should never be exploited for their entertainment value alone (Maple 2016). However, the very real need for human beings to get closer to animals is not all bad. Zoo operators will have to be very creative to find safe and ethical ways to encourage some form of contact that is good for the animals, our caregivers, and the public.

In the latter years of the twentieth century, accredited zoos began to back away from the word "zoo." Bronx Zoo changed its name to the Wildlife Conservation Park and the venerable

New York Zoological Society adopted the name Wildlife Conservation Society (WCS), the name it goes by today. Zoo professionals didn't really dislike the zoo label but worried about the nuanced meaning of the word given the many imposter facilities known as "roadsides." The industry also experimented with other names, for example, Albuquerque, New Mexico's use of Michael Robinson's hybrid nomenclature "BioPark." A field biologist by training, Dr. Robinson created the label and defined it when he was director of the Smithsonian National Zoological Park. North American zoos have also begun to reverse their names following the lead of many European zoos, e.g., Zoo Atlanta and Zoo Miami follow the form of Zoo Cologne and Zoo Zurich. Choosing to put the word "zoo" first suggests you are not ashamed of it. Finally, many others chose to expand their vision to include botanicals as in "Jacksonville Zoo and Gardens." These efforts were all designed to promote the noble core values of zoos and differentiate them from low-budget entertainment competitors. After the success of many theme parks with animals, SeaWorld, Busch Gardens, and Disney's Animal Kingdom, many zoos experimented with rides to generate additional income. Train rides and carousels were always a part of zoo culture, but chimpanzee tea parties and elephant rides have been discredited and abandoned. Children's petting zoos are also in decline due to safety and health issues. Reputable zoos continue to search for balance between contact with and distance from animals in the collection. Cleveland Metroparks Zoo recently announced it would permit visitors to meet and hold a 16-foot, 17-pound Burmese python in their reptile house. Supervised by several keepers to ensure safety, the experience was designed to reduce fear and promote appreciation for snakes.

## The First Priority

Historically, the first major shift in zoo priorities was the institutional commitment to conservation. This change was revolutionary in its effect as world zoos achieved unprecedented levels of

cooperation to coordinate reproduction in zoos and to protect biodiversity and the vulnerable ecosystems that support it. Some individual institutions have demonstrated unusual attention to global conservation. The Wildlife Conservation Society, based in New York City at the Bronx Zoo, has long operated successful field conservation programs in 59 countries. To carry out this work, WCS has amassed a significant endowment that continues to grow. Other elite zoos such as the Frankfurt Zoological Garden and the Zoological Society of London have independently taken this path with both of them playing an active global role as investigators and institutional supporters to protect biodiversity hotspots worldwide. Conservation partners such as Conservation International (CI) and the World Wildlife Fund (WWF) have expressed their appreciation for two strategic priorities that contribute to conservation. First, zoos continue to generate significant funding to support conservation efforts in cooperation with non-governmental organizations. Second, by exhibiting exotic wildlife in naturalistic facilities, zoos also inspire and educate the public which helps to shape governmental policies on the environment.

Zoos also support conservation by active, formal partnerships. For example, a unique working relationship between Zoo Atlanta and the Dian Fossey Gorilla Fund International was established when the nonprofit conservation organization relocated to Atlanta from its former location in Denver in 1995. Since that time, the zoo has provided rent-free space, technical support, and volunteers on its campus, and DFGFI has prospered. The current CEO, Dr. Tara Stoinski, graduated from the doctoral program in psychology at the Georgia Institute of Technology and worked simultaneously for the zoo and the fund for many years until she was named to lead the organization. Zoo Atlanta's 50 years of working with captive lowland gorillas in partnership with Yerkes National Primate Research Center has generated more research on this species than any other world zoo. To commemorate its achievements, the Association of Zoos and Aquariums awarded Zoo Atlanta its prestigious Bean Award for long-term propagation. DFGFI's presence in Rwanda is succeeding in the field by providing protection

for a growing resident gorilla population, and the organization has recently expanded to support the smaller *Grauri* population in Congo. In addition to its success in protecting wild gorillas, DFGFI is also contributing to the economy of Rwanda and Congo.

## Global Cooperation

Organized globally under the umbrella of the World Association of Zoos and Aquariums (WAZA), zoos have come to understand their potential impact on the survival of wildlife populations and habitat. Only by working together in an organized way, can leaders, members, donors, collaborators, and sponsors of zoos expect to change the world. If we fail to find the antidote to habitat degradation; illegal poaching; trading in body parts such as bones, ivory, and horn; the bush meat trade; and illegal capture for exhibition, the natural world will be left in ruin for our heirs. Global cooperation is not easy to initiate or sustain but the alternative of going it alone will never succeed. Zoo leaders are increasingly engaged in acts of diplomacy and persuasion, but sometimes they must act together to shame another institution if it goes rogue.

Acknowledging their successful transformation from entertainment to committed conservation organizations, a second priority to advance animal welfare standards and practices has emerged. This priority is no longer subordinate to conservation but is now regarded as synergistic and of equal importance. In fact, it is widely believed that if zoo visitors are not comfortable with the way zoo animals are exhibited, they will not return nor will they support the other priorities of the offenders or recommend them to others. The welfare of zoo animals is regarded as a significant driver of zoo achievements in education and conservation. As important as animal welfare has become, zoos have recently sought to upgrade their commitments to achieve a higher standard of welfare. This upgrade has been identified as "wellness" or, alternatively, "optimal animal welfare" (Maple and Bocian 2013; Maple and Bloomsmith 2018). The goal of this shift is to

encourage zoo animals to thrive rather than merely cope with the artificial conditions of captivity. All accredited zoos and aquariums have moved aggressively to eliminate any vestiges of suffering, but elevating the bar from coping to thriving is the current challenge. The global campaign to convert zoos to softer simulations of natural habitats has proved to be costly, and comprehensive change cannot be accomplished overnight. Fortunately, there is a reservoir of superior design ideas and plenty of talented landscape architects to revitalize even the most dilapidated facilities. In countries where the design revolution has not yet caught on, advocates of reform need to step up their game to rally public and private support on behalf of animals living in less than ideal settings.

### Wellness-Inspired Design

Wellness-inspired design is changing the way zoos look and function. This design approach complements and advances prior innovations such as landscape immersion and activity-based design (Coe 1985). The wellness construct expands the opportunities we provide for animals to engage with their environment, interact with appropriate groups of conspecifics, live in stratified societies, move about freely in sufficiently large and complex spaces, search for diverse food sources, solve mental and physical problems daily, and live a relatively autonomous social life with few limitations. Some have called this outcome “a life worth living.” Given the considerable progress zoos have made, it is still fair to conclude that there remains widespread welfare inequality in our institutions. For example, some species such as many reptile taxa have been underserved by exhibit innovation and welfare services. A glaring example is the impoverished exhibits that prevail for giant snakes such as pythons, boids, and anacondas (Maple and Perdue 2013). However, as scientific zoo biologists begin to focus on underserved populations, results have been encouraging. For example, Bashaw and her colleagues (2016) conducted laboratory experiments to demonstrate that leopard geckos respond

favorably to environmental enrichment, while Brando and Burghardt (2019) have confirmed that many reptiles are playful. Hundreds of studies of animal play were carried out by anthropologists (Smith 1978), comparative psychologists (Maple and Zucker 1978), and developmental psychobiologists (Baldwin and Baldwin 1978) before the first serious study of play in reptiles was documented.

### Fewer Species/Living Well

It was once fashionable to flaunt the size of your animal collection to win high marks from peers. The absolute number of animals or species is no longer important; instead, zoos and aquariums earn respect for their stewardship of rare and endangered species and their ability to manage them in socially appropriate, species-typical groupings. Responsible zoos no longer choose to exhibit singletons such as the solitary gorilla or elephant, anachronisms of a less enlightened bygone era. Modern zoos are finding ways to exhibit fewer species that live better than ever before. Specialization sometimes takes the form of theming zoos to their region, for example, the Arizona-Sonora Desert Museum, a highly successful, accredited AZA facility. Northwest Trek Wildlife Park in Eatonville, Washington, is a 723-acre facility exhibiting bison, elk, mountain goats, and other animals indigenous to the Pacific northwest of the United States. The animals in these facilities are adapted to living in the warm and cool climates of these two respective regions. It is no longer acceptable to exhibit a polar bear in a southern zoo where it is likely to turn green from algae or suffer from the extreme heat.

### The Empirical Zoo

The importance of evidence-based exhibition, husbandry, and management is supported by all professional zoo biologists, educators, and administrators. Although there are some artistic elements at work in zoos, empirical zoo biologists have successfully solved many of the most vexing

problems that once plagued the profession. Assisted reproduction, genetic analysis, nutrition, behavior pathology, aggression, and mate selection have all required scientific systems and inquiry to generate solutions in animal husbandry. Pandas did not breed in captivity until western and Chinese scientists began to work together to solve the problem; gorillas didn't thrive in zoos until normal social groups were established; physical abnormalities in horned ungulates persisted until inbreeding coefficients were calculated and understood. One of the most significant achievements of the AZA/SSP program in the 1980s (Perkins and Maple 1990) was the successful karyotyping of the entire North American population of Bornean, Sumatran, and hybrid orangutans. Although many zoos have yet to invest in formal scientific programs, they all benefit from those that do. Powerhouse research programs at Brookfield and Lincoln Park in Chicago (Erwin et al. 1979), San Diego Zoo Global, and Smithsonian National Zoological Park are generating a stream of data to help all zoos manage their animal collections. Australia, Germany, and the United Kingdom have also become international centers of excellence for evidence-based husbandry and management. Another positive trend is the fact that college and university scholars are discovering zoos as living laboratories of biodiversity for faculty and students with an interest in the sciences. Currently, Australia and New Zealand are two of the most active world centers for advances in animal welfare. The pace of innovation in Australia is impressive with leaders, young and old, who are now active in the World Association of Zoos and Aquariums, and many other relevant NGOs.

### **Elevated Standards and Practices**

To encourage serious reforms in world zoos and aquariums, zoo executives have tried to influence the way zoos are operated and the way they are perceived by the public. The high priorities of education, conservation, and welfare have replaced entertainment as the focus of our master

plans. We understand that zoos must be designed to bring out the best in animals and we must work with them in a humane and ethical fashion to provide the highest quality of life possible. To do this zoos must become experts on a massive variety of biodiversity from insects to reptiles to birds to mammals to fish and the plant species that form the context of their habitats. Hediger stated that research was always last in the zoological garden, certainly the least funded and appreciated priority in most zoos. However, animal welfare standards would not have been achieved if research had not driven the agenda and investigated the issues and risks associated with the use of animals by humanity. Therefore, science/research cannot possibly be last in the zoological garden, and it is today much more important than it seemed in Hediger's time. Other than the strong trend to naturalistic, immersive design, and the commitment to the highest standards of medicine in all zoos, the advance of zoological institutions as centers of excellence for biodiversity research is the strongest trend of all.

### **Lifetime Commitment**

From the intensity of animal welfare science occurring globally, new standards and better practices have led to profound changes in our commitment to quality of life. One of these changes is the commitment to care for our animals for life. We are obligated by our ethical standards not to abandon an animal because it is no longer young or beautiful. We must continue to value the lives of sick and injured animals as long as they are not suffering. Retirement too must be handled with care. In Atlanta, we retired an old male lion who had one eye. I had hoped he would be able to live in a new exhibit with younger females, but our veterinarian advised me that the females would endanger his life or severely injure him if they fought him. To protect him, we found a vacant yard at the back of the zoo but provided him with as many amenities as we could. Despite his limitations, he retired gracefully and remained an important and valued member of our zoo population. By this action, we confirmed that every

animal that serves our community has value for the entirety of its life.

### The Lesson of Marius the Giraffe

In 2011 the zoo world erupted in controversy due to the decision of Copenhagen Zoo authorities to euthanize a healthy, young adult male giraffe that was genetically overrepresented in the zoo population. Since he was not going to breed in the future, the zoo elected to separate him from other giraffe and determined that he was welfare-compromised. Reluctantly but decisively, they elected to publicly shoot him, dismember the carcass, and feed the body parts to the lions. The act was widely regarded as cruel and brutal, although Copenhagen staff defended the action, utilized the experience in educational programs, and received little opposition from local citizens. However, the event played badly internationally, and print and electronic media offered a cacophony of criticism and scorn. The event also divided the zoo profession as zoo leaders, scientists, educators, and veterinarians took sides on the issue. Insiders at the World Association of Zoos and Aquariums agreed that the incident had been divisive and sowed dissention within the association. To our Danish colleagues, the decision was an ethical one, but any objective observer would have to conclude that it was a public relations disaster. The only silver lining from this experiment in management euthanasia is that it generated greater understanding about population control in zoo collections. There are some situations where culling animals makes sense. In animals that have huge numbers of eggs or offspring, spiders, for example, a curator may have no choice but to eliminate some of the stock because there is no demand. The argument can be made, however, that zoos should be more prepared to deal with surplus in a humane and ethical manner. Too many zoos in recent years solved their surplus ungulate problem by donating animals to hunting ranches. In the United States when this happened in 1999, a hostile media onslaught lowered public confidence in zoos that engaged in this unethical practice and blamed others who had not. I faced a similar dilemma

when I was director of Zoo Atlanta and a pair of gigantic reticulated pythons unexpectedly presented us with 60 live offspring. It seemed a miracle birth at first as it was a first breeding for this species at our 100-year old zoo. Upon reflection, however, I learned that the only demand for these animals was the pet trade. I would not agree to send them into this marketplace knowing they would someday become 30-foot predators of small dogs, cats, and possible children, or they might become a hungry invasive species roaming the Everglades in Florida when pet owners ceased to be amused by them. I made the painful decision to humanely euthanize them when they were small and vowed to be more careful in the future. The lesson learned here is that responsible zoos must thoughtfully plan their collections and breed only those that can live well after birth at the zoo or in a suitable distant destination of comparable quality.

### From Coping to Thriving

In a recent publication, Maple and Bocian (2013) examined the differences in animal welfare and wellness. The latter construct had not previously been used in the animal welfare literature, but it had a strong presence in the domain of human health and wellness. Historically, animal welfare, based on decades of serious research, had generated information to assist decision-makers in government and in professional associations to upgrade the living standards of animals utilized in agriculture, biomedicine, and exhibition worldwide. In our commentary in the journal *Zoo Biology*, we observed that animal welfare was originally regulatory in response to shortfalls in the standards and practices in these fields. In addition, to render reforms more practical, the new regulations tended to be minimal and achievable. By contrast, wellness was aspirational with no clear limits on how well a subject could become. We reasoned that if people wanted to be optimally well, as healthy and well as they could be, then why not use this reasoning for captive animals? This was the first time we suggested that zoos ought to aim higher in setting their goals for

**Zoo, Fig. 1** Directional outcome of higher zoo standards. From Maple and Bocian (2013)

standards and practices. As wellness has gained traction among zoo professionals and academics, animal welfare has gone from good to great, as zoos began to accept nothing less than optimal wellness as their objective. In explaining the evolution of wellness, we traced these outcomes from suffering to coping to thriving. No zoo tolerates suffering in their population of zoo animals, but most zoo animals are coping, more or less, with captivity. We have written and continue to believe it is time for all zoos to acknowledge that thriving is the preferred standard of living for animals serving humanity in accredited zoos and aquariums. This standard will be difficult to attain for all animals in the collection, but it is the right objective to pursue (Fig. 1).

### Charismatic Megafauna

Zoos and aquatic parks have also struggled with the challenge of exhibiting charismatic megafauna such as elephants, hippopotamus, polar bears, giant pandas, and killer whales. SeaWorld's reputation was hurt when the sensational documentary film "Blackfish" was televised to a massive audience of disbelievers. The report alleged a history of abuse and mismanagement including a failure to disclose the true risk of swimming with these dangerous predatory animals. Although the company denied the claims of the film's producers, the general public lost their enthusiasm for performing whales. Throughout the world, performing marine mammal shows have been closing due to public and government opposition to the apparent exploitation of cetaceans strictly

for their entertainment value. Dolphin programs that have survived public pressure have been particularly careful to give their animals sufficient freedom to choose whether to play or be left alone, and show programs have been tailored to protect the dignity of the performing animals. In the Far East, performing whales and those living in passive exhibits do not generally live well, and high mortality and morbidity is common. A major concern for the exhibition of marine mammals such as belugas and orcas are the stressful and often lethal forms of capture they have endured. For this reason, many importations have been denied by federal wildlife agencies in the United States and other countries. As a corporation, SeaWorld is committed to combining education and entertainment, and they are the most successful private aquatic enterprise engaged in the rescue and rehabilitation of sea mammals. Their reputation may be tarnished, but they are by no means down for the count.

Similarly, zoological parks have endured criticism for errors in their acquisition and exhibition of giant pandas on loan from China. In the 1980s, world zoos began to acquire pandas on short-term exhibition loans that generated money quickly. So many zoos were renting the animals that the World Wildlife Fund and the US Department of the Interior was alarmed that zoos were "loving them to death." Worse yet, the program spun out of control when shopping malls and casinos expressed their interest in short-term loans of pandas. In 1985 the "rent-a-panda" program was suspended by the US Department of the Interior, and it took 10 years to restructure an improved loan program. The first pandas imported to the San Diego Zoo in 1996 generated one million US dollars for conservation projects in China during its first year of operation with Interior monitoring the exclusive use of these funds. The San Diego loan was followed in sequence by loans to Zoo Atlanta, Memphis Zoo, and the Smithsonian National Zoological Park. Currently, the US giant panda exhibition program has generated more than \$50 M to support panda conservation and research programs. Although few zoos can afford to pay the fees to exhibit them today, the

panda experiment demonstrates that a model for exhibition can be found that supports rather than exploits the survival of this species.

With respect to polar bears, scientific studies have determined that these bears need to roam widely to be considered healthy and well. Most zoo exhibits are not large or complex enough to offer satisfying living conditions. There are some exceptions such as the Detroit and St. Louis Zoos and the Point Defiance Zoo & Aquarium in Tacoma, Washington, where polar bears appear to be thriving. Boris, at Point Defiance, at 33 is one of the oldest polar bears in captivity. The Arctic tundra exhibit was one of the nation's first exhibits to model the natural habitat of this northern species using the grassy tundra of Point Hope, Alaska, as a guide. A highly unusual polar bear exhibit was opened by the Town of Cochrane, Ontario, Canada, designed by the zoo, Ted Maranda, and a team of architects from the firms ANO architects and Ursa International. The exhibit was positioned as a sanctuary for surplus polar bears in this remote region. The facility has two contiguous 1-acre habitats and a fenced 16-acre lake within it. It is one of the most spectacular polar bear exhibits ever conceived by the mind of zoo designers.

Another long-neglected species is the Nile hippopotamus, ubiquitous in world zoos but rarely provided with sufficient space or natural opportunities that fit its species-typical habits in the wild. Having visited many zoos throughout the world, only a few of them provide hippos with optimal welfare and many facilities border on suffering. While a consultant at the San Francisco Zoo in 2011, I worked with a graduate student from the University of California at Davis on a survey of hippo habitats in North American zoos. Kristen Denninger and I carried out an initial survey and then decided to replicate and expand it when I returned to Florida to work at the Jacksonville Zoo and Gardens. The Jacksonville wellness group, under my direction, took on this replication and published it (Tennant et al. 2018). The data confirmed our initial findings that the vast majority of North American hippo exhibits failed to deliver good welfare. Except for the superior exhibit at

Disney's Animal Kingdom, very few zoos exhibit groups of hippos, typically pairs and singletons. Two notable exceptions to the rule are the Hippoquarium at Toledo Zoo and San Diego's underwater hippo exhibit. Both provide plenty of space and splendid underwater viewing opportunities for visitors to watch them gracefully move their huge bodies in the water. In Africa, Nile hippos live in large groups at the river's edge in shallow water. They locomote in the water during the heat of the day, coming out to sunbathe on mudbanks in the afternoon. At night hippos leave the water en masse and forage on the grassy shores. Safari campers near rivers in Africa often see hippos slowly moving through the camp at night and bellowing. They return to the water early the next morning, and this is when they are most dangerous to humans. Africans who choose to wash their clothes in a river must be aware of returning hippos who will pursue them. Hippos kill more people than any other African animal. Knowing what we know about them, it would be expensive but relatively simple to simulate their natural behavior. With a riverine simulation that is 121 m. in length, Disney has provided a stimulating habitat for its resident hippos. If Disney wanted to breed them, they have sufficient space to do it. Because there is no demand for hippos, most zoos don't want to breed them, but they can be segregated in captivity to simulate the natural condition. The males are much larger than females. When hippos are confined to small night houses at the end of the day, they are deprived of the natural opportunities that meet the definition of thriving. Our paper documented the fact that hippos are among the most neglected zoo animals. We need to do better to enhance their quality of life with larger exhibits and holding facilities. Zoos that cannot meet their needs should not exhibit them.

Ten years ago, zoo elephants were in as much trouble as hippos except they received more attention and publicity for the deficiency of their exhibits. The treatment of elephants in substandard zoos was truly scandalous and generated very bad publicity. The chronic foot problems of elephants living on broken concrete were

endemic. Worse, elephants killed a number of their caregivers in zoos and circuses during the late twentieth century forcing the AZA and other associations to rethink their exhibits and their management standards. Forced to spend millions for corrective action, many zoos simply closed their exhibits and abandoned their elephants to sanctuaries. The highly respected Bronx Zoo decided to retire their elephants in place with no plans to replace them when they die. Woodland Park Zoo in Seattle, known for its exhibit innovations in the late 1970s, also decided to close its elephant exhibit and translocate their animals to another AZA facility. Others, however, accepted the challenge of building better exhibits, and the improvements achieved in recent years are praiseworthy indeed. In Dallas, applying the motto, “let elephants be elephants,” planners built a large and highly complex outdoor habitat with contiguous trails that encouraged them to walk as much as 5 miles per day. They also spent money to provide a better barn with a soft substrate to ease the pressure on their tender joints. A large full immersion pool gives them relief, and caregivers work with the animals to provide enrichment and attention without dominating or stressing them. Dallas and many other zoos have found the formula for providing superior surroundings and exemplary care for elephants. Even bulls are doing better. Birmingham Zoo in Alabama pioneered the management of multiple bulls and proved that older bulls seem to mentor younger ones. If zoos are afraid or unprepared to exhibit bulls, we put them at a social disadvantage, and they suffer poor welfare. We have to find a way to build strong facilities to withstand their sheer power but still provide amenities and opportunities for them to be socialized with the herd or with other males. The Birmingham experience (Braccini-Slade 2019) is supported by data from studies of wild bull elephants in Africa (Evans 2019). Elephant exhibits at the world’s best zoos, such as Cologne, Dublin, and Zurich Zoos and many other North American zoos, are a major success story for the zoo profession, but there are still many zoos that have not reformed their approach to elephant exhibition and welfare.

## Assessment of the Great Debate

Zoos worldwide have organized to meet growing demands from the public, animal welfare and rights organizations, and governments to meet higher standards of animal welfare for zoo and aquarium animals. The body of criticism has been both reasonable and irrational. The most vociferous critics advocate an end to captivity in all its forms. Mark Bekoff (2008) has demanded that zoos and aquariums stop their organized breeding programs because he believes offspring simply multiply the population of suffering animals through no fault of their own. This is a shocking conclusion by a well-published animal behaviorist who ignores the positive trends evident in the modern zoo profession. To make things worse, he actually promoted this idea to a gathering of serious zoo professionals and animal welfare scientists. Unfortunately, his statement went unchallenged, but it should be challenged. The California Condor has been rescued from the brink of extinction by organized breeding efforts of the San Diego and Los Angeles Zoo. Offspring from these birds now fly freely in California although they are still vulnerable to human interventions such as habitat encroachment, pesticides and poisons, illegal poaching, and collisions with human technologies. In addition to saving them through assisted reproduction technology, western zoos advocate for their protection. One of the western zoo partners, Santa Barbara Zoo, invests resources in studying the reintroduced birds in the field and operates an excellent condor exhibit with considerable space for the captive birds to help inform and influence public opinion. Advocacy for conservation is one the primary purposes of all accredited zoos. The exemplary public record of achievement of world zoos in conservation science, education, and animal welfare is available to anyone who is interested in learning the facts. Our recently published book *The Scientific Foundation of Zoos and Aquariums* (Kaufman et al. 2019) and *The Ark and Beyond* (Minteer et al. 2018) published by University of Chicago Press provide strong evidence that zoo professionals and their academic

collaborators are seriously committed to upgrading the exhibition and care standards and practices of world zoos. Those who study these documents will find that accredited, achieving zoos and aquariums are worthy of their support as visitors, donors, members, and sponsors. With the public's help, good zoos are getting better and better. Although I strongly believe that accredited zoos are moving in the right direction, the debate about their value is likely to continue. I am not concerned about the zoos that are leading reform and revitalization, but I am greatly concerned about the thousands of "mom and pop" facilities that call themselves zoos but do not deserve our support or patronage. Zoo professionals engaged in reforming zoos are only interested in operating superior institutions that inform, inspire, and excel.

Other constructive forums have succeeded in producing conclusions that have become guides to industry benchmarks. At the Atlanta meeting that culminated in the Smithsonian book *Ethics on the Ark* (Norton et al. 1995), zoo professionals were persuaded by animal welfare scholars to make a greater commitment to individual animals rather than populations. This simple shift in attitude facilitated the next few decades of reform and revitalization in our nation's accredited zoos. Clearly, responsible constructive criticism, even when it comes from outside the profession itself, can lead to substantive change. It is important to understand that significant reform is generated by zoo professionals themselves as they study their options and investigate how they can obtain better results for the benefit of the animals and our communities. Zoo administrators continue to seek input and advice from visitors, volunteers, business authorities, and community leaders. Zoo professionals are eager to advance the quality and purpose of their profession. While Americans appear willing to give their local zoo an opportunity to rehabilitate and reform, many other nations are rapidly closing zoos and banning animal entertainment such as circuses and shows. The wealthiest and best-known circus in the world, Ringling Brothers, recently ended its use of elephants in the circus and will now retire the entire collection.

## World Zoos and Mental Health

Environmental psychologists have gathered sufficient information about the positive effects of nature that government agencies are attempting to design communities with greater amounts of green and blue space. Trees, plants, and grasses are examples of green space; blue space is comprised of water features, oceans, lakes, rivers, and streams. In a recent chapter in an important book by Ann Devlin (2018), Maple and Morris (2018) suggested that the power of green/blue space could be extended to include naturalistic zoos, aquariums, and botanical gardens. There is a robust body of evidence that such places support human mental health in a variety of ways. Particularly in highly urbanized parts of the world, there is a need for urban oases where human populations can gather for respite, relaxation, and revitalization. The love of nature is so strong in our species that we have defined a new field of architecture known as "biophilic design" (Kellert 2018). Zoos, aquariums, museums, and botanical gardens are venues where biophilia prevails.

## Marketing Core Values

The organized opposition to zoos and aquariums is a worldwide phenomenon and unrelenting. Much of it is also extreme and uninformed. Accredited zoos must devote their time and financial resources to combat the misinformation with credible public campaigns of their own. Sophisticated social marketing techniques have been employed in public media advertising, but the best approach may be point-of-sale inoculations. Within the zoo itself, it is essential that zoos share their core values and demonstrate their firm and enduring commitment to protect wildlife in every way they can. This means paying attention to how animals are responding to the most creative new exhibits and systems and generating increasing amounts of human and financial capital to support field conservation. If operated properly, modern zoos will be centers of education and inspiration second to none, and they will be valued and utilized in their communities. Outmoded hard

architecture is no longer acceptable in the zoo profession, so virtually every zoo must be evaluated, reimagined, and rebuilt to fit our noble objectives in public education, conservation, and community engagement. Zoos must continue to demonstrate that they are good for animals and people and a beneficial investment for communities, cities, and nations. In the best zoos, information is passed to the public by employees and volunteers giving formal and informal demonstrations in the vicinity of the enclosures or behind the scenes. Wellness exams can be given to big cats from outside the barriers by signaling for cooperation by the cats who lean on the mesh and permit a look by the caregiver or the vet. Effective training transforms zoo animals into good patients and a good day at the zoo. With proper training for compliance and care, working with wild animals has become a much safer occupation.

### Launching Ethical Arks

The North American zoos that are leading the way on animal welfare include Brookfield and Lincoln Park in Chicago, Detroit, Oakland (CA), Disney's Animal Kingdom, Jacksonville Zoo and Gardens, Oregon Zoo, San Diego Zoo Global, and San Francisco Zoo. There is considerable progress in Europe, and strong leadership is coming from Zoos Victoria and Sydney Zoo in Australia. The latter country is home to many academic programs that are advancing animal welfare in agriculture, biomedicine, and zoo biology (Hemsworth et al. 2011). Aquariums have been less successful in discovering reforms to support animal welfare. The challenge of exhibiting and managing charismatic aquatic megafauna is daunting even for large corporations like SeaWorld. One serious problem with aquariums in the Far East is their propensity to acquire whales and other marine species through highly questionable methods and means. The demand for marine mammals is high in Asia, and strong reforms and regulations are needed. Even large fish such as whale sharks are vulnerable in artificial manmade holding tanks, swimming endlessly in circles. Except for the relatively successful

Georgia Aquarium exhibit, whale sharks do not seem to be good candidates for aquatic exhibition. If whales are to be exhibited in future facilities, the standards will have to be dramatically elevated. Compared to zoos, aquariums suffer much greater mortality and morbidity in their collections, and their populations must be regularly replenished through open-ocean retrieval. Many of the most difficult ethical questions facing the zoo and aquarium industry have been highlighted in a new book by Dr. Jenny Gray, CEO of Zoos Victoria and current Chair of the board of WAZA. *Zoo Ethics: The Challenge of Compassionate Conservation* (2017) is setting the global agenda for zoos and aquariums rapidly moving ahead of public expectations.

### The Bright Future of Zoos

Some observers have predicted a dim future for zoos (Hancocks 2001), but it is far more likely that zoos will follow the path of innovation and discover better ways to present wildlife in human care. Reform is already occurring at a rapid pace. Hancocks is an architect who led three major zoos as CEO, so he knows that good zoos can be created, but it takes substantial time to turn a zoo around by design and development. Except in periods of economic uncertainty, as in the year 2008, innovative exhibits have been opening each and every year. One of the most exciting prospects for future zoos and aquariums is their scientific value as guardians of biodiversity. Zoos are living laboratories, but they are not isolated from their evolutionary history in physically and socially sterile laboratories. The trend to naturalistic immersive exhibits and facilities bring them into focus as seminatural field stations where animal behavior is comparable to what is seen in free-living populations (Coe and Mendez 2005). As teaching laboratories for young biologists and psychologists, zoos serve a purpose that is unmatched by any other setting. This has become especially important as institutions of higher learning have abandoned macrobiology education in favor of microbiology. Students can spend 4 years as undergraduates without ever studying

a whole living organism let alone social animals because these populations are simply not available on campus. Field stations such as the national primate centers in Atlanta, California, Oregon, Washington, Louisiana, New England, and Wisconsin have been extremely important assets in higher education, but they are few and far between. Our nation's elite zoos and aquariums represent a more accessible resource if formal working partnerships can be arranged with universities. It is an exciting time for students of comparative cognition as we are learning more each day about the extraordinary cognitive capacity of animals. Zoos collect, exhibit, and manage animals that have never been studied by comparative psychologists or ethologists. As the record demonstrates, zoo animals are increasingly assigned as subjects in ethological and comparative psychological research. A good example is the collaboration between Dr. Meredith Bashaw, a professor of psychology at Franklin and Marshall College, who carried out original research on the social structure of giraffe at the San Diego Wild Animal Park (Bashaw et al. 2007).

Beginning with Harlow and Yerkes' pioneering work with animals in private institutions including zoos (Maple 1979), and Duane Rumbaugh's research at San Diego Zoo, many other facilities have stepped up to offer their subjects for comparative studies including Brookfield and Lincoln Park in Chicago, Indianapolis Zoo, SeaWorld, and Zoo Atlanta. In Atlanta, many colleges and universities continue to carry out cognitive studies of great apes as the legacy of Zoo Atlanta's historic scientific partnership with the Yerkes National Primate Research Center. At the Smithsonian National Zoological Park, comparative psychologist Ben Beck designed and supervised the execution of "Think Tank" the first North American zoo exhibit devoted to the history of comparative cognition research. Research by psychologists at SeaWorld in recent years reminds us of the distinguished history of cetacean learning research by pioneers such as Louis Herman, Karen Pryor, Ron Schusterman, and Stan Kuczaj. Fortunately, many of these pioneers left a legacy of students to continue their work. Other important contributors from

venerable institutions such as the Language Research Center of Georgia State University are advancing the legacy of Professor Rumbaugh under the direction of his former student, David Alan Washburn. In addition to his work at the field station, Professor Washburn has contributed important ideas to the field of animal welfare (Washburn 2015). Recent symposia organized in the southeast to honor Duane Rumbaugh's scholarship and leadership have brought together new generations of colleagues to share ideas and plan future projects. Enormous intellectual contributions have resulted from Franz de Waal's interest in the mentality of zoo primates (De Waal 2006). Starting with his work in Netherlands' Arnhem Zoo, he worked on bonobo sociality and cognition at Milwaukee County Zoo, San Diego Zoo, and in Atlanta at Yerkes. Professor de Waal is one of two zoo biologists who are elected members of the prestigious US National Academy of Sciences. The other is Professor Jeanne Altmann of Princeton University and formerly associated with Brookfield Zoo (Maple and Bashaw 2010). We can look forward to exciting discoveries ahead as more zoo resources are committed to the cause of science and growing numbers of academics are recruited to collaborations with zoo biologists.

As the public becomes more aware of the core values and interests of their local zoological parks, attendance and financial support is sure to grow. Zoos are already more popular than professional sports especially with families, and they are unique in blending learning with recreation. If zoos commanded the television and radio presence of sports, the public would be beating down the doors to get in. The best evidence of reform are the exhibits themselves and the exemplary condition of the resident species. Although animals are not active at all times, the way they are presented even when they are peacefully asleep makes a strong impression. Animals can be activated through training if they are not disturbed, stressed, dominated, or overworked. However, research indicates that animals prefer work to getting food for no effort and they benefit from human companionship, attention, and interaction. Zoos are getting better at these transactions. As centers of excellence for discovery, education,

conservation, and inspiration, modern, high-quality zoos and aquariums are proving they are worthy of our strong support.

## Zoological Association of America (ZAA)

Kathleen N. Morgan  
Wheaton College, Norton, MA, USA

### Synonyms

[ZAA](#)

### Definition

A nonprofit accrediting organization for wildlife parks, zoological facilities, animal sanctuaries, aquariums, and animal rehabilitation centers.

The Zoological Association of America is a nonprofit accrediting organization established in the early 2000s through the merger of two other related organizations, the International Society of Zooculturists (ISZ) and the United Zoological Association (UZA). With the Association of Zoos and Aquariums (AZA), the ZAA is one of the primary accrediting bodies in the United States for zoological facilities, aquariums, animal rehabilitation centers, wildlife parks, and animal sanctuaries.

Part of the motivation for the merger and the formation of a second accrediting body for those holding exotic animals in captivity was the concern expressed by private breeders and some other publically owned animal collections that their needs and views were not adequately represented by the only accrediting organization available at the time – the AZA. While the ZAA addresses these concerns perhaps more directly than does the AZA, the ZAA does not accredit private exotic or wild animal pet owners.

ZAA's written mission statement describes it as an accrediting organization “dedicated to responsible wildlife management, conservation, and education.” As of the time of this writing, it had approximately 500 members and over 60 accredited member facilities. The organization engages in a captive breeding management program across its member facilities aimed at enhancing genetic diversity in captive populations.

Like AZA, the ZAA hosts an annual conference, a midyear conference, and issues grants to conservation organizations around the world. It also publishes a quarterly newsletter and journal, the *ZAA Journal*. Additional information about this organization can be found at its website, <http://zaa.org/>.

## Zoology

Carolina Carvalho Cheida<sup>1</sup> and

Luiz Eduardo Cheida<sup>2</sup>

<sup>1</sup>Instituto Conservação Brasil, Chapada dos Guimarães, MT, Brazil

<sup>2</sup>Cidade Solar, Lodrina, PR, Brazil

Zoology or animal biology is the branch of biological sciences that studies structure, classification, and distribution of **animals**. It covers areas of systematics, anatomy, morphology, physiology, embryology, cytology, genetics, evolution, ecology, ethology, zootechnics, and paleontology (Soares 1993; Figueiredo et al. 2013; Holley 2015).

Living beings can be grouped into different categories, from kingdom to species. Kingdom is the category of greater comprehensiveness, bringing together living beings of similar characteristics, with peculiarities. According to classification proposed by the biologist R.H. Whittaker, in 1969, the alive beings are classified in five great kingdoms: Monera, Protista, Fungi, Plantae, and Animalia.

It is believed that the **animal kingdom** was originated in the archaeozoic oceans long before the first fossil record. From the ancestral marine environment, different groups of animals were formed and, some, little by little, moved from fresh water to dry land, further expanding the diversity of their species.

The term **species** (Latin *type*) is one of the categories proposed by the Swedish naturalist, Carolus Linnaeus (1707–1778) in his book *Systema Naturae* (1735), where he suggests a system of classification of living beings. In this system, species is the basic category of this classification. Similar species can be grouped into one **genus**. Genera with similar characteristics are grouped together to originate a **family**. Several families with similar characteristics are grouped into **orders**, and, similarly, orders are grouped into **classes** and classes in **phyla**. Phyla, in turn, are grouped in **kingdoms**.

One of the great merits of Linnaeus was to associate a nomenclature with classification. His classification system is **binomial**, meaning it has two names. The first name corresponds to the genus and the second to the species (**epitet**). *Homo sapiens*: genus *Homo*; species *sapiens*.

However, such a system is hierarchical and based on morphological characters. Currently, studies have used the **phylogenetic systematics** or **cladistic taxonomy**, a classification that organizes the species according to their evolutionary kinship.

From an evolutionary point of view, species diversity is one of the consequences of the diversity of biomes and ecosystems inhabited by them. Charles Robert Darwin (1845–1896) explained the diversity of species as a product of **natural selection** and **evolution**. His works were better understood and complemented from the twentieth

century, when the mechanisms of **genetic inheritance** formulated by Gregor Johann Mendel (1822–1884) were finally understood.

Humans have always sought to learn about animals. Certainly, at the outset, the main purpose was to distinguish those suited to their own diet. Soon, some came to be feared, others, dear ones and some more, adored, with their figures being used to symbolize Gods. The domestication of some brought advantages to humans such as territorial guard, alert against predators and human opponents, locomotion, and tasks that required force.

Zoology as a **science** arose in Greece, about 350 BC through the *History of Animals*, book of Aristotle (384–322 BC). In this book, the author made observations about anatomy, social organization, and embryology and he attempted the first known animal classification, grouping them as *animals with blood* (known nowadays as **vertebrates**) and *animals without blood* (**invertebrates**).

Today, zoologists study animals in several situations: in free living, in controlled experiments in laboratories, and in museums and collections. Thus, there are many areas of specialization within the zoology: **protozoology** (the study of Protozoa), **entomology** (insects), **ichthyology** (fishes), **herpetology** (amphibians and reptiles), **ornithology** (birds), **mastozoology** (mammals), and **parasitology** (parasites and their hosts).

Although there is a high diversity of animal species in the world, many face a population decline and even extinctions caused mainly by anthropic actions, such as destruction of habitats, pollution, predatory hunting and fishing, among others. Therefore, knowledge about existing species is an essential part of biodiversity conservation.

Today, there are over 2.5 million animal species already described and 10 to 30 million to be discovered. Of these, about 5% represent animals that have a serially arranged spine or vertebrae and a bony or cartilaginous endoskeleton. These animals are called **vertebrates**. The other 95% of species that do not have backbone are **invertebrates**.

Animals are multicellular beings, with **eukaryotic** cells, without cell walls and that, in most cases,

form tissues. However, they vary enormously among themselves: the body symmetry can be **bilateral**, **radial**, or **pentaradial**. In some of them, the body is set in repeated units, called **metamer**. Nutrition is **heterotrophic**, with extra- or intracellular digestion. The breath is **aerobic**. They can be sessile or move through feet, legs, wings, and fins or, still, by body contraction. Most have sexual reproduction, producing gametes. There may be sexual dimorphism: male and female are physically different. **Dioecious** or unisexual, when each individual has one sex, and **monoecious** or bisexual or hermaphrodite when an individual has both sexes. Their fertilization is internal or external. Development can be direct, when it does not have larval stages, or indirect when it goes through larval stages before becoming adult. The embryonic leaflets in the **diploblastic** species are the ectoderm and endoderm; in the **triploblastic** species are ectoderm, mesoderm, and endoderm. The coelom is absent in the **acoelomates**, partially coated by the mesoderm in the **pseudocoelomates**, or totally delimited by the mesoderm in the coelomates. In the **protostome**, the blastopore gives origin to the mouth and in the **deuterostome** to the anus.

## Invertebrates

The phyla representing the living invertebrates are briefly described below (according to Ruppert and Barnes 1996; Cheida 2002; Holley 2015).

### Phylum Porifera

Sponges.

Animals with the simplest structure of the animal kingdom. They have a body pierced by pores and supported by a skeleton of protein fibers or silica or limestone spicules. There are three basic types of sponges, from the simplest to the most complex: **asconoid**, **syconoid**, and **leuconoid**. Most have radial symmetry. They live alone or in colonies. They are sessile, which means, fixed on the ground or on rocks, corals, or shells, in marine or freshwater. Nutrition is heterotrophic, with intracellular digestion. Respiratory system is aerobic, with diffusional gas exchange. Its

excretion is through the upper opening, the **osculum**. They have no nervous system. Most reproduce sexually, with indirect development, through the larvae. There are monoecious and dioecious sponges. There are species that reproduce asexually by fragmentation, budding, or producing gemmules.

### Phylum Cnidaria

Hydrants, jellyfish, caravels, corals, and sea anemones.

They are exclusively aquatic: predominantly marine but also freshwater species. The body is polyp-like, like a tube with fixed base and an upper portion with mouth and tentacles, or in the form of jellyfish, medusa-like, movable with tentacles or arms. They have radial symmetry. They are carnivores, feeding on fish and zooplankton. They are aerobic, by diffusion, as well as the circulation of nutrients and gases between cells. Excretion occurs within the gastrovascular cavity and is eliminated by the mouth. Jellyfish move through water jets, caravels float through pneumatophores, and polyps float through somersaults. The nervous system appears for the first time and is of the diffuse type. They are carnivorous, with extra- or intracellular digestion. They are monoecious or dioecious. There is asexual reproduction, by budding, in the polyps and sexual in the jellyfish. Indirect development forms the seedling larva. In the epidermis are **cnidocytes**, cells that contain oval capsule (**nematocytes**) containing toxic substance and a rolled filament in the form of javelin; when touched, the capsule breaks, releasing the dart soaked in the toxic substance, injuring the prey. The phylum is divided into three classes: **Hydrozoa** (hydras and caravels), **Anthozoa** (sea anemones and corals), and **Scyphozoa** (jellyfish). Some anemones have **mutualism** with certain fish or with hermit-crab. Coral reefs are formed by anthozoans and harbor immense variety of living beings.

### Phylum Ctenophora

Seahorses or comb jellyfish.

Marine animals, gelatinous, almost transparent, of coastal waters. They have eight rows of ciliary combs that propel the body for locomotion.

They favor pelagic invertebrates, capturing them by retractile tentacles present in many species. They are hermaphrodites.

### Phylum Platyhelminthes

Flatworms and planarian.

They represent the **first organisms with bilateral symmetry**, a body organization apparently more efficient than the others. The body is flattened dorsoventrally. They are free living or parasites. Carnivorous, herbivorous, or parasitic heterotrophs. The digestive system is incomplete, with extra- or intracellular or absent digestion, as in tapeworms. Breathing is aerobic and circulation occurs by diffusion. For the first time, in some species, a **rudimentary excretory system** occurs. The nervous system is composed of longitudinal nerve cords. They are hermaphrodites, with asexual or sexual reproduction.

### Phylum Nemertea or Rhynchocoela

Ribbon worms or proboscis worms.

They comprise small to large worms, elongated and often flattened. The **proboscis** and ciliated epidermis capture food. Most are marine benthic, but there are deep-sea pelagic species. They live in cracks in rocks, under rocks, or in clumps of seaweed. They move by ciliary movements, peristalsis, or both. They are invertebrate predators. Gas exchange occurs through the body surface. They have specialized coelom, exclusive of this phylum. The nervous system is formed by ganglionic brain and ocelli. Dioecious, the reproduction occurs through external fertilization and direct development.

### Phylum Rotifera

Rotifers or wheel animals.

They are predominantly part of freshwater zooplankton where they promote nutrient recycling. There are species who are freely swimming, creeping, sessile, and colonial. The benthic species swim through a crown of hair and use adhesive glands on the tips of their feet to attach to the substrate. The body is transparent. Dioecious or parthenogenetic females. Development is indirect. In adverse conditions, they remain in **cryptobiosis**.

### Phylum Acanthocephala

Acanthocephalans, thorny-headed worms, or spiny-headed worms.

They are endoparasites, requiring two hosts to complete their life cycle (when juveniles, they parasite crustaceans and insects; when adults, they parasite the digestive tract of vertebrates, especially fish). Retractable proboscis with spines is used to attach. They do not have a digestive tract, absorbing food through their body wall. They are dioecious.

### Phylum Gastrotricha

They represent freshwater and marine species, most of them microscopic. The body is shaped like a bowling pin or is flattened ventrally. They feed on bacteria through a sucking pharynx. Hermaphrodites, with internal fertilization and direct development.

### Phylum Entoprocta

They cover few species, predominantly those sessile with tentacles. They were part of the phylum Bryozoa, but, unlike those, the coelom is absent and there is no exoskeleton. Most are marine, except for a single freshwater genus. They live attached to rocks and shells or have a commensal relationship with bryozoans, polychaetes, sponges, and other animals. They live alone or in colonies. They have a pair of **protonephridia**. Hermaphrodites. Many species incubate their eggs.

### Phylum Tardigrada

Water bears.

Small animals that live up to 70 years in soils, beaches, mosses, and lichens present in rocks and trees. The plump body is smooth or segmented with four pairs of ventral legs with discs or claws. Their locomotion is slow, creeping, and their claws fix them to the substrate. They feed on vegetables, seaweed, and debris, with the help of two mouthpieces and a sucking pharynx. Food travels through the pharynx to the intestine, where it is digested and absorbed; its last portion, the rectum, connects to a terminal anus. They have a dorsal brain and ganglion nerve cords attached to sensory organs (**bristles**). Most are dioecious. Parthenogenesis is common. Development is

direct. In adverse conditions, they remain in **cryptobiosis**.

### Phylum Nematoda

Ascarids, roundworms, hookworms, pinworms, and whipworms.

Animals of cylindrical body, elongated, with bilateral symmetry and sharp edges. Most are parasitic on animals and vegetables. There are several parasitic nematode species of great medical and economic importance. Many terrestrial species suck up commercially important plant roots, causing damage. *Ascaris lumbricoides* parasites the intestines of several species, including humans, and can reach 49 cm. **Filariasis** or **elephantiasis** is a severe parasitic disease caused by *Wuchereria bancrofti*. Due to their mouth and anus, a **complete digestive system** appears for the first time on the animal scale. The digestion is extra- and intracellular. Breathing is aerobic, with diffusional gas exchange. Excretion occurs through an excretory pore. The locomotion occurs through longitudinal musculature. The nervous system is rudimentary. Most species are dioecious. Reproduction is sexual, with internal fertilization for most and direct development. In adverse conditions, they remain in **cryptobiosis**.

### Phylum Nematomorpha

Horsehair worms and Gordian worms.

They are long worms of 5 to 10 cm. Free-living species in freshwater and moist soils from temperate and tropical regions. The only marine genus (*Nectonema*) parasites crabs and shrimps. Their larvae parasitize beetles, locusts, crickets, and centipedes. Dioecious, with internal fertilization.

### Phylum Kinorhyncha (Ancient Phylum Echinoderida)

Mud dragons.

Small group of marine species. It lives in the mud or between grains of sand. Its main characteristic is the segmentation of the tough cuticle. There are species with adhesive tubes on the ventral surface. At the tip of the buccal cone there are oral stiletos, and the head can retract, also moving the body when it digs. They feed on organic material. Dioecious, with direct development.

### Phylum Loricifera

Marine animals with size of 1/4 mm. So heavily adhered to grains of sand and other substrates that the attempt to separate does not result in living organisms to be better studied. Its anterior extremity is conical and spiny (**scalid**), retracting within a posterior region wrapped in a **lorica** (abdomen). They are dioecious. Little is known about their systems and lifestyle habits.

### Phylum Priapulida

Priapulid worms.

Benthic, deep, or shallow waters. They live buried in mud or sand. Found in Antarctica and the tropics. They are shaped like a cylindrical trunk with retractile, swollen, and thorny proboscis in the anterior portion, used to dig and capture prey. They are carnivorous and bacterivorous. Animals do not have a vascular-blood system. They have nervous system inside the epidermis, with non-ganglionar brain and ventral nerve cord also non-ganglionar. Dioecious, with external fertilization in larger species and probably internal in the smaller ones.

### Phylum Annelida

Ringed worms, earthworms, leeches, and polychaetes.

Animals of elongated body, cylindrical, and metamerized by external and internal rings, defining its name. Complete digestive system, with carnivorous, herbivorous, or parasitic diet. Breathing occurs through gas exchange by diffusion. The circulatory system is closed. A pair of nephridia, located in each segment, shapes the excretory system. They move by body contraction. They may be dioecious, with sexual reproduction, external fertilization, and indirect development, or monoesters with cross-fertilization and direct development. Earthworms, by revolving the soils, have great importance in agriculture.

### Phylum Mollusca

Octopuses, squid, slugs, snails, snails, oysters, and mussels.

They have a soft body that defines their name. Most have a limestone shell for support

and protection. They are the **first coelomates**. Head, foot, and visceral mass form the body. Most are carnivorous, but there are herbivores. The digestive system is complete. Respiration can be through lung, gill, or cutaneous. The circulatory system is open or lacunar type. Excretion occurs by nephridia. For locomotion, terrestrial animals use the foot, and marine animals use mainly propulsion. The nervous system has ganglia united by nervous cords. They are dioecious or monoecious, with cross-fertilization, internal or external. Development is direct or indirect.

### Phylum Arthropoda

Insects, spiders, scorpions, shrimps, crabs, centipedes, and others.

It is the largest phylum of existing animals, living in terrestrial or aquatic habitats. They have articulated paws, and their body is covered by chitin shell called exoskeleton. The exoskeleton needs to be discarded periodically so that the animal can grow, a phenomenon called molting or ecdysis. They are metamerized in the head, thorax, and abdomen, and, in arachnids and crustaceans, head and thorax merge into cephalothorax. Its digestive system is complete with extracellular digestion. The respiratory system in the insects is **tracheal**; in arachnids it is **philotracheal** and in ticks **cutaneous**. The circulatory system may be open or lacunar. The excretory system in insects occurs through **Malpighian tubules**, in crustaceans through **green glands**, and in arachnids in **coxal glands**. They are sessile, like barnacles, or furniture, like the others. Nervous system formed by nervous ganglia. Dioecious and have internal fertilization (most insects and arachnids) or external (crustaceans). The development is direct (arachnids) or indirect (insects and crustaceans). Mosquitoes, flies, butterflies, beetles, grasshoppers, cicadas, dragonflies, bedbugs, ants, bees, and termites represent the **Insecta** class, considered the most biodiverse. Other major classes are **Crustacea** (lobster, crab, garden tattles), **Arachnida** (spiders and scorpions), **Chilopoda** (centipedes), **Thoracica** (barnacles), and **Diplopoda** (snake lice).

### Phylum Echinodermata

Starfish, sea urchin, sea cucumber, sea lily, sea snakes, and others.

Exclusively marine and free life. They have **endoskeleton** and great capacity of regeneration. They move through **ambulacral system** (with the exception of the sea lily). The ambulacral system consists in channels through which water enters, circulates, and leaves, providing locomotion, breathing, and feeding. They are carnivorous or herbivorous, with complete digestive system and extracellular digestion. Breathing occurs through gills (starfish and hedgehogs) or respiratory trees (cucumber). The excreta are eliminated by diffusion through the ambulacral system and gills. The circulation occurs in the channels within the coelom. The nervous system is diffuse. They are dioecious, with no sexual dimorphism. Fertilization is external with indirect development.

### Vertebrates

Vertebrates live in practically every habitat on Earth. They have a high diversification, due to more than 500 million years of evolution, probably beginning in the seas of the Cambrian Period. The basic plan of the body consists of a bilateral tubular organization, formed by notochord, pharyngeal clefts, hollow dorsal nerve tube, vertebrae, and skull. Following, the classes representing the present vertebrates and nearby taxa (Hemichordata, Urochordata, and Cephalochordata) are described (according to Hildebrand 1995; Pough et al. 1999; Schmidt-Nielsen 1999; Cheida 2002; Holley 2015).

### Phylum Hemichordata

Acorn worms.

Small animals, exclusively marine. They have gill slits and a supposed notochord that classifies them near the Chordata. *Balanoglossus* is the main genus studied. It has a tripartite body in the proboscis, collar, and trunk, or **protosome**, **mesosome**, and **metasome**. Sessile or of little movement. There are species that crawl and dig with proboscis; others live on the surface, feeding on phytoplankton and organic matter from the

sediments. The circulatory system is developed, with a contractile organ called the **cardiac vesicle**. A reticulated nervous plexus forms the nervous system. Reproduction is **gonochoric**, with external fertilization.

## Phylum Chordata

Chordate.

Animals with common features, as **notochord**, **gill slits in the pharynx**, and **dorsal nervous system**. Some are invertebrates, such as lizards, amphioxus, and lampreys, and witches represent the **Protocordados**. The others are vertebrates and classified as **Eucordados**.

Chordata comprises three subphyla: Urochordata, Cephalochordata, and Vertebrata (or Craniata).

### Subphylum Tunicata (Urochordata)

Ascidians.

Tunicates are marine exclusive. Both sessile and free-living, live isolated or in colonies. They are covered by a thick cuticle called **tunic**. Notochord is present only in larval form. They have an incomplete digestive system. They feed on plankton filtered by the pharynx and processed in the stomach and intestine. They breathe through gas exchange through **pharyngeal clefts**. The circulatory system is open, although there are blood vessels and heart. They are monoecious, with external fertilization and indirect development, or reproduce by budding.

### Subphylum Cephalochordata

Amphioxus or lancelets.

Exclusively marine, live buried in the sand. They have notochord throughout life, formed by striated muscles (**myomeres**). Complete digestive system. The food is collected by filaments, the **buccal cirrus**. They feed on plankton. Gaseous exchanges occur through the skin or through filtered water through the pharynx. The circulatory system is open, with no heart. The excretory system is composed of **protonephridia**, formed by **flame cells** that absorb the products of excretion. The nervous system has the cerebral vesicle. Dioecious, with external fertilization and indirect development.

### Subphylum Vertebrata or Craniata

Wizards, lampreys, cartilaginous and bony fish, amphibians, reptiles, birds, and mammals.

The common feature of all vertebrates is the replacement of the notochord in the vertebral column and the presence of a skull that protects the brain. They inhabit aquatic and terrestrial environments. Following, the classes that represents the vertebrates.

### Class Agnatha Lampreys and hagfish.

They are known as **jawless fish** or **cyclostomes** for not having a jaw, but a **circular mouth**. Hagfishes are marine and lampreys live in fresh or marine water. Their body is cylindrical and elongated, and cartilaginous plates form its spine. They have a **cartilaginous skeleton** and the notochord, present only in adults, has a supporting function. Their skin is smooth with **mucous glands** and dorsal and caudal fins. In the mouth, hagfishes have **tentacles** and lampreys have a **sucking mouth**, tongue, and horny **teeth**. Complete digestive system and intestine with bowel folds in spiral (**typhlosole**). The liver aids in chemical digestion. They are parasites. Lamprey sucks the tissues of a prey in which it adheres, by suction and with its teeth. Hagfishes can penetrate weakened fish through its gills and anus and also feed on dead animals. Breathing occurs through gills: water enters the gill slits, mouth, or nostrils, and gases are carried by **hemoglobin** in the blood. Circulation is simple and complete. Blood is pumped from a heart with two chambers into the gills. The excretory system consists of **pronephric** or **mesonephric** kidneys. The product of excretion is ammonia. Ripples of the body result in movement. The nervous system has encephalon and medulla, sensory organs such as **eyes** and **inner ear** (body balance), and tactile cells in the epidermis. Dioecious, with external fertilization and direct development in hagfishes and indirect in lampreys.

### Class Chondrichthyes Sharks, rays, and chimeras.

They are fishes, mostly marine, with **cartilaginous skeleton** and pectoral, pelvic, and caudal **fins** that aid in displacement and defense. Rays also have a stinger in the pectoral fin. They secrete

mucus through epidermal cells by reducing friction with water. Their skin is thick, coated with **placoid scales**. The digestive system is complete, with **ventral mouth** with several rows of **teeth**. Esophagus, stomach, intestine, liver, gallbladder, and pancreas assist digestion. Most are carnivorous, but the whale shark is a filter feeding. The respiratory system is branchial: water and oxygen enter through the mouth, pass through the gill slits, and exit through a pair of **spiracles**. Their circulation is closed and simple, with a heart formed by an atrium and a ventricle. The erythrocytes contain **hemoglobin**. **Mesonephric kidneys** collect urea and ammonia from the blood, eliminating them by the cloaca. The nervous system consists of the brain, cranial nerves, and spinal cord. Fertilization is internal. Males have modified pelvic fin (**clasper**), whose function is to introduce sperm into the female cloaca. They are oviparous, ovoviviparous, or viviparous, with direct development.

#### **Class Osteichthyes** Bony fishes.

They are aquatic vertebrates with **bone skeleton**. Inhabit salt water and freshwater. Move through pectoral, pelvic, median dorsal, anal, and caudal fins. The digestive system is complete, with mouth at the anterior end, **conical teeth**, esophagus, stomach, intestine and anus, liver, pancreas, and eventually gallbladder. The respiratory system is gill, with four pairs of gills protected by **opercula**. The circulation is closed and simple, with a heart composed of two chambers. They have **mesonephric kidneys**, urinary bladder, two ureters, and urogenital pore that excretes ammonia. Nervous system is composed of the brain, cranial nerves, and spinal cord. They are **heterothermic** or **poecilotheurmic**, varying their internal temperature according to external. Fertilization is internal or external. They are oviparous or ovoviviparous. The development is direct or indirect, with formation of **larvae**.

#### **Class Amphibia** Anura (frogs and toads), Urodela (salamanders), and Apoda (caecilians).

They have two phases of life: one aquatic and one terrestrial. First vertebrates to live in **terrestrial** environment and first **tetrapod** of the animal kingdom. They have moist and smooth skin, with

**mucous glands**, forcing them to inhabit also moist places. Most live in aquatic and terrestrial habitats (including arboreal or fossorial habitat environment), although some species are exclusively terrestrial or aquatic. They are predators, with a complete digestive system: mouth without teeth in most species, a protractile and sticky tongue to catch prey, esophagus, stomach, intestine, liver, pancreas, and cloaca. Breathing occurs through gills in the larval stage or throughout life in some species of aquatic salamanders. In adult phase, respiration is cutaneous, although there are primitive lungs that aid in the process. The circulation is closed, double, and incomplete, and the heart has three cavities (two atria and one ventricle). Kidneys mesonephric, ureters, bladder, and cloaca excrete **ammonia** in the larval stage and **urea** in adults. They move through swimming during the larval stage and jumping, crawling, or walking when adults. The nervous system is composed of the brain, cranial nerves, spinal cord and spinal nerves. Vision is developed, except in caecilians. Frogs have in the head the paratoid gland, producer of poison. Dioecious, with indirect development in most species, originating the tadpoles. As their eggs do not have shell, they are protected by gelatinous substance and by the moist or wet environment where they are deposited. In most species, there is copulation, although the fertilization is external, except for salamanders and caecilians, whose fertilization is internal.

#### **Class Reptilia** Turtles, tuataras, lizards, snakes, and alligators.

First animals to settle, definitively, on **land**. Determinant for this was the development of an egg with a shell resistant to desiccation and, internally, embryonic attachments such as vitelline sac, amniotic pouch, and allantois, which reproduce to the embryo the aquatic environment from which their ancestors came. Dry skin covered by horny plaques on crocodiles and alligators, shells in turtles, and scales on snakes and lizards. Complete digestive system, from mouth to the cloaca. They are carnivores, like crocodilians, snakes, and tuatara, or herbivores, like some chelonians and lizards. Important adaptations for feeding are sharp teeth in crocodilians, cutting jaws in chelonians, and ability to disarticulate the jaw and dilate the

stomach or have **venom-inoculated prey** such as snakes. Respiratory system consists of nasal cavities, larynx, trachea, bronchi, lungs, and alveoli. The circulation is closed, double, and incomplete. The heart is composed of four chambers: two atria and two ventricles, these not completely closed. Kidney metanephros, ureters, mostly a urinary bladder, and cloaca eliminate uric acid. The locomotion is made by fins (tortoises), muscle contraction (snakes and lizards), and feet in terrestrial species, where there may also be horny or sucker claws. The nervous system is composed of cranial nerves, encephalon, spinal nerves, and spinal cord. The sensory system consists of two **nostrils** and **Jacobson's organs**, located on the palate and receiving **odorous** particles picked up by the tongue. Some snakes have two **sensitive pits** in front of the eyes where they perceive **thermal variations**. They present the **middle ear** and **tympanum**, the last one absent in snakes. Eye protection is exerted by the **nictitating membrane** and tear glands, especially in snakes (which as no eyelids). They are **heterothermic**, varying their internal temperature according to the external temperature. Dioecious, with internal fertilization and direct development. Most are oviparous. Some species are ovoviviparous. Snakes have a bifurcated penis (**hemipenis**).

### Class Aves Birds.

They have **feathered bodies**, **horny beaks**, and anterior limbs turned into **wings**. The feathers, exchanged annually, are formed by keratin and guarantee flight aerodynamics, thermal insulation, and protection against desiccation. Porous bones, with air inside them (**pneumatic bones**), form the skeleton. **Pneumatic cavities** are lung projections into these bones, leaving the bird lighter for flight and assisting internal cooling. Absence of teeth and urinary bladder also make the animal lighter. In flying birds, the sternum bone is keeled, connecting the wing muscles. The eyes are externally lined by a transparent membrane (**nictitating membrane**), which prevents dryness during flight. The **urophygial gland**, next to the cloaca, produces oily secretion which waterproofs the feathers. The feet are covered by epidermal scales. They inhabit the most varied terrestrial and aquatic environments, living alone

or in flocks. Their diet can be frugivorous, carnivorous, detritivorous, granivorous, insectivorous, nectarivorous, piscivorous, or omnivorous. The digestive system is complete: beak, tongue, salivary glands, dilated esophagus, **crop** (stores and moistens food), **proventriculus** (chemical stomach), **gizzard** (specialized muscle in crunch), liver, pancreas, small intestine, and cloaca. Breathing occurs in two lungs without alveoli. Songbirds have the **syrix**, the organ responsible for singing. The circulatory system is closed and complete: heart with four chambers (two ventricles and two atria). Kidney metanephros, ureters, and cloaca excrete uric acid. Few species have urinary bladder. In seabirds, excess sodium chloride from food is eliminated by the **salt gland**, located between the eyes. The nervous system consists of the brain, cerebellum, cranial and spinal nerves, and spinal cord. They are **the first homeothermic beings**, keeping the internal temperature constant, even with variations in the external temperature. **Sexual dimorphism** is observed in most species, males having generally more vibrant colors. After a **courtship display** period, performed by males in most species, mating occurs. They are dioecious, with internal fertilization and direct development. Oviparous, the eggshells have calcium carbonate and embryonic attachments similar to reptiles.

**Class Mammalia** Platypus/Ornithorhynchus, echidnas (both Prototheria-Monotremata), kangaroos, opossums (both Metatheria-Marsupialia), armadillos, anteaters, tapirs, rats, bats, canids, felids, rabbits, whales, primates (as humans), and others (all others Eutheria-Placentalia).

Animals with **mammary glands**, **hairs**, differentiated teeth, and **diaphragm** and **homeothermic**. Free-living animals, living alone or in groups or complex social organizations. The skin contains **sweat**, **sebaceous**, and, in some species, **odoriferous glands**, for defense. Dermal and epidermal dermis form, in addition to **hairs**, scales, plaques, beaks, horns, claws, and **nails**. They inhabit terrestrial and aquatic environments. Their diet varies by species. The digestive system is complete, beginning in the mouth and ending in the anus, except for the monotremates that have **duck-billed** and **cloaca**. They have salivary

glands, except in aquatic mammals. Ruminants (bovines, sheep, goats, giraffes, and others) are adapted to the cellulose digestion, with stomach divided into four chambers: rumen, reticulum, omasum, and abomasum. **Lungs** with alveoli, aided by the diaphragm, do breathing. The larynx has **vocal folds** that allow the emission of sounds. The circulatory system is closed and complete, with two atria and two ventricles, and erythrocytes with hemoglobin as the respiratory pigment. Two kidney metanephros, ureters, urinary bladder, and urethra excrete **urea**. They move by walking, swimming, flying, and gliding, through feet, fingers, hooves, fins, wings, and membranes. The nervous system is the most developed of the animal kingdom, composed of the **brain**, cranial nerves, spinal cord, and spinal nerves. Bats and aquatic mammals, such as whales and dolphins, use **ultrasounds** to aid in locating obstacles and searching for food. They are dioecious, with internal fertilization and direct development. This development occurs, for most placental species, in the **uterus** of females, where embryonic attachments are formed. Marsupials, like the kangaroo, complete their development in the **marsupial**, after leaving the uterus still embryonic. In both cases, they are **viviparous** mammals. Monotremates, such as the platypus and the echidna, which lay eggs, are **oviparous** mammals.

## Zoonoses

Lisa Lauderdale  
Chicago Zoological Society – Brookfield Zoo,  
Brookfield, IL, USA

## Synonyms

[Zoonotic diseases](#)

## Definition

Zoonoses (also known as zoonotic diseases) are any naturally transmitted disease or infection between humans and nonhuman animals.

## Introduction

Zoonoses (zoonosis, singular) are infectious diseases caused by viruses, bacteria, fungi, parasites, or prions that are transmissible between human and nonhuman animals through food, water, air, environment, or direct physical contact. Reverse zoonosis, or anthroponosis, occurs when a human infects an animal. In rare cases, these diseases can reinfect humans from the animal reservoir. For example, swine are susceptible to infection with

swine, avian, and human influenza viruses. If a pig is infected with influenza viruses from different species simultaneously, the viruses can mix and create a new virus that can reinfect humans. Diseases such as elephantiasis and African schistosomiasis are sometimes mistakenly thought of as zoonotic, even though they are transmitted via animal vectors, part of their natural life cycle requires a human host, and therefore are not considered zoonotic.

Humans and nonhuman animals coexist within a complex network of interactions. These interdependent relationships result in exposure to a wide range of pathogens that cause an equally diverse range of diseases and symptoms. Animals that appear to be healthy, or subclinical, are still capable of transmitting pathogens that can infect humans. Zoonotic diseases in humans and animals can result in anything from mild symptoms to death.

Zoonoses represent a significant global health burden. Approximately 61% of pathogens known to infect humans are zoonotic (Taylor et al. 2001), and 75% of emerging infectious diseases in humans are zoonotic in nature (Jones et al. 2008). The escalation in emerging zoonotic pathogens is due to increased contact between humans and animals (Daszak et al. 2001). Human activities are continually expanding into wilderness areas and wildlife and, in turn, are increasingly moving into urban areas. Additionally, the development of livestock farming operations has escalated the amount and closeness of human-animal interactions.

## Zoonotic Pathogens

There are a vast number of different zoonotic pathogens, which allow for transmission of disease from many different nonhuman animal vectors to humans. Pathogens spread via unprotected contact with infected agents and between closely related hosts such as humans and other nonhuman primates. Other mammalian species most commonly infect humans; however, nonmammalian vertebrates, as well as invertebrates, can also be sources of infection. Infectious agents include

bacteria, viruses, prions, protozoa, fungi, and arthropods. Pathogens can be acquired through ingestion, inhalation, or physical contact. Pathogenic organisms are found in skin lesions, body fluids, secretions, and excretions of their respective animal hosts and spread directly through animal vectors or indirectly through their byproducts, such as contaminated food.

Human consumption of undercooked meat, unpasteurized milk, raw eggs, and contaminated vegetables is a common route of infection for zoonotic pathogens and results in a large number of foodborne diseases in people. According to the Centers for Disease Control and Prevention, bacteria and viruses were the most common cause of foodborne diseases in the United States in 2016 (<https://www.cdc.gov/foodborneoutbreaks/>). *Salmonella* and *Campylobacter* caused the most illnesses, hospitalizations, and deaths followed by *Shigella* and *Cryptosporidium*. Some foodborne diseases, such as *Norovirus* (Norwalk virus) and *Clostridium perfringens*, are usually only identified in major outbreaks.

## Routes of Transmission

The increase in human-animal contact has resulted in a surge of emerging zoonotic diseases (Jones et al. 2013). The prevalence of livestock farming and the rising global human population makes it unlikely that human contact with wildlife will decrease in the near future. The interdependent relationship between humans and animals leads to more vectors of transmission. One method for classifying zoonoses is by categorizing them based on one of four main routes of transmission: direct contact, indirect contact, vector-borne, and foodborne.

Direct zoonoses are transmitted by coming into direct contact with the blood, saliva, skin, bodily fluids, urine, or feces of an infected animal. Scratches and/or bites from an infected animal also represent forms of direct contact transmission. For example, Q fever, caused by *Coxiella burnetii*, can be contracted through the inhalation of infected feces, and *Salmonella* can originate from direct handling of infected amphibians or

reptiles. Nontraditional or exotic pets carry a relatively high risk of being vectors for transmission. In fact, an outbreak of monkeypox occurred due to the importation and distribution of a species of African rodent as pets.

Zoonoses can be transmitted via indirect contact as well. Intermediate species (called vectors) can be carriers of a disease, without being infected themselves, and indirectly transmit the pathogen to a human host. Humans can also be indirectly infected through exposure to environments in which infected animals have been present. Humans are infected through contact with contaminated bedding, aquarium water, plants, soil, and coops or barns. For example, pathogens such as *Toxocara* spp. and *Sporothrix schenckii* reside in soil, and adults and children can become infected while gardening or playing outside.

Vector-borne diseases are infections transmitted to humans by the bite of infected arthropod species, such as mosquitoes, ticks, triatomine bugs, sandflies, or blackflies. For example, ticks transmit the causative agent of Lyme disease, mosquitoes spread diseases such as malaria and dengue fever, while the triatomine bug and sandflies are the vector species for Chagas disease and leishmaniasis, respectively. According to the World Health Organization (WHO), vector-borne diseases cause more than 700,000 deaths annually (“Vector-borne diseases” 2017).

Foodborne zoonoses are transmitted through the consumption of contaminated food or liquids. Infectious agents can be bacteria (e.g., *Campylobacter*), viruses (e.g., hepatitis A virus), parasites (e.g., *Trichinella*), or prions (e.g., bovine spongiform encephalopathy). Eating or drinking unpasteurized milk, undercooked meat or eggs, raw seafood, or contaminated fruits or vegetables can all cause illness. The WHO estimates that one in six people in the United States gets sick from foodborne illnesses each year. Foodborne trematodiasis are examples of zoonoses that cannot be transmitted directly as they are only infectious to humans after having completed a complex life cycle in an intermediate nonhuman host.

Transmission via any of these routes can take place in any context in which human and non-human animal environmental overlap exists. The relationship can be based on companionship (pets), economics (livestock production), predation (hunting and fishing wildlife, animal attacks), or medical factors (researching medications and vaccines).

## Risk Factors

The connections between humans, animals, and their environments are a source of zoonoses that can impact public health and the world economy. While anyone with direct or indirect contact with animals is at risk of becoming infected, many factors play a role in an individual's susceptibility to a zoonosis (Shakespeare 2009). Certain populations are more likely to be infected by specific zoonoses based on their geographic location, occupation, socioeconomic status, age, or immune health. Generally, young children, elderly, pregnant, and immune compromised individuals are at a high risk of infection. Those who hold occupations that require close contact with animals, particularly jobs involving animal carcasses, are more likely to be in contact with zoonotic pathogens. Some zoonotic diseases are more prevalent in specific geographic locations or climates. For example, trematodiasis are more common in East Asia and South America, while the burden of vector-borne diseases such as malaria weighs most heavily on tropical and subtropical climates and disproportionately affects the poorest populations. Diseases such as bovine and porcine brucellosis, bovine tuberculosis, and rabies are well controlled in developed nations but remain significant problems in developing ones.

The effects of zoonotic diseases on public health place a significant burden on the global economy (Jones et al. 2008). Risk factors can be mitigated through a variety of economic and social changes. The implementation of responsible agricultural and farming practices can reduce the transmission of zoonotic disease. Improving

sewage waste disposal systems and reducing standing water in urban areas can greatly improve rates of vector-borne infections for large populations. Access to health care and preventative treatments can decrease rates of illness and death, especially in rural populations.

## Zygote

Priyanka Verma

Department of Molecular and Human Genetics,  
Banaras Hindu University, Varanasi, India

## Synonyms

Fertilized ovum; First diploid cell of new organism

## Definition

Zygote is the fertilized ovum, which is the fusion of two haploid gametes (male and female pronucleus).

## Main Text

Zygote formation is an intricate and synchronized array of dynamic events, which is elicited by sperm and oocyte interaction (Niakan and Eggan 2013). Basically, it includes sperm penetration, subsequent calcium oscillations in oocytes followed by oocyte activation, sperm and oocyte fusion, development of male and female pronucleus, genome-wide epigenetic reprogramming, and migration of pronucleus to the central position followed by oocyte to zygotic transition (Papale et al. 2012). The zygote is a unicellular entity, and it comprises all the genetic information that is essential for growth of the new organism. Zygote formation process is known as fertilization.

## Pronuclear Formation

Pronuclear (PN) formation is the important event for zygote formation, which involves re-establishment of nuclear envelope of both the sperm and oocyte. PN formation is classified into six stages, i.e., PN<sub>0</sub>–PN<sub>5</sub>: PN<sub>0</sub>, sperm entry

followed by completion of meiotic arrest of mature oocyte, decondensation of sperm and second polar body eliminates; PN<sub>1</sub>, initiates demethylation; PN<sub>2</sub>, demethylation activates in paternal genome, while maternal genome is resilient; PN<sub>3</sub>, demethylation is complete; PN<sub>4</sub>, two nuclear polar bodies (NPBs) move close together; PN<sub>5</sub>, both the NPBs are adjacent to each other before syngamy (Papale et al. 2012).

The presence of two centrally positioned, juxtaposed PNs with clearly defined nuclear membrane along with two polar bodies is used for the evaluation of normal fertilization. Nowadays, PN scoring of zygote technique is used in the in vitro fertilization procedure. Aberrant PN number in any stage, i.e., PN<sub>1</sub>–PN<sub>5</sub>, is observed, which is considered as low viable pregnancy and not transferred in infertile females (Papale et al. 2012). Transition from oocyte to zygote involves mRNA translation, which is essential to start a new life and organelle remodeling. Studies suggest that meiotic machinery molecules regulate oocyte to zygotic transition. After this transition, the zygote starts to divide mitotically and develop into a multicellular organism.

## Epigenetic Reprogramming of Zygote

In genome-wide reprogramming specially demethylation, methylation is an important epigenetic event in both the primordial germ cells and early embryonic stages, respectively (Fraser and Lin 2016). Several evidences have shown that global and active demethylation patterns by TET-3, BER, elongator, and Stella are found in the paternal genome, whereas global and passive demethylation patterns by Stella have been found in the maternal genome (Stitzel and Seydoux 2007). This reprogramming has direct influence on pluripotency, erasure of epimutations, regulation of paternal imprinting, and transcriptional control of transposons in the zygote (Schultz 1993).

After the fusion of germ cells, the zygote restores diploid number of chromosome 2n. From the zygotic chromosome basis, we can identify the sex of the embryo/fetus, e.g., oocyte has X sex chromosome and either X or Y will be coming from the spermatozoon. If the zygote has XY sex chromosome, it is genetically male, and if XX, it is genetically female (Wassarman 2001).

## Conclusion

Hence, the zygote is considered first biologically alive and a unicellular entity, which has potential for metabolism, growth, reaction to stimuli, and reproduction.
